Siler, Joseph F., capt., ordered to proceed from New York City to Peoria, Ill., and return, on business connected with the Medical Department.

Drake, Percy G., 1st lieut., M. R. C., ordered to proceed from Fort Ethan Allen, Vt., to Fort Leavenworth, Kan., for temporary duty.

Morse, Arthur W., major, relieved from duty at the Presidio of Monterey, Cal., and ordered to the Philippine Islands, for duty on Oct. 5, 1909.

Parce, Alexander D., 1st lieut., Wilson, James A., 1st lieut., relieved from duty with Co. C., Hospital Corps, Fort Niagara, N. Y., and ordered to the Philippine Islands for duty on Oct. 5, 1909.

Trotter-Tyler, George, 1st lieut., M. R. C., relieved from duty at Vancouver Barracks, Washington, and ordered to the Philippine Islands, on Oct. 5, 1909.

Winter, Francis A., major, Darnall, Carl R., major, Pipes, Henry F., capt., appointed members of a board of officers of the Medical Corps, to meet at the Army Medical Museum Building in Washington, at the call of the senior member of the board, for the purpose of conducting the preliminary examination of applicants for appointment in the Medical Corps of the Army.

Wickline, Wm. A., capt., granted 30 days' leave of absence.

Ekwurzel, George M., capt., granted leave of absence for three months, to take effect on his relief from duty in the Philippines Division.

Schmitter, Ferdinand, 1st lieut., granted leave of absence for four months, with permission to go beyond the sea.

Shillock, Paul, major, relieved from treatment at the Army and Navy General Hospital, Hot Springs, Ark., and will return to his proper station.

Howard, Deane C., major, granted two months' leave of absence, to take effect on his arrival in the United States.

Juenemann, George P., capt., granted 10 days' leave of absence Aug. 19.

Ames, John R., *dental surgeon*, accompanied by a member of the Hospital Corps, as assistant, will proceed from Fort Snelling, Minn., about Sept. 1, 1909, to the following named posts in the order given and report to the commanding officer for temporary duty during the period indicated to perform dental work for officers and enlisted men: Fort Lincoln, N. D., 15 days, Fort Assinniboine, Mont., 30 days.

Scott, Harold O., *dental* surgeon, relieved from duty in the Philippines Division, and on arrival at San Francisco, to report by telegraph to the Adjutant General of the Army for further orders.

Medical Corps of the Navy

Changes for the week ended Aug. 21, 1909:

Robertson, G. E., acting asst.-surgeon, ordered to duty at the Naval Hospital, Boston.

Ledbetter, R. E., surgeon, detached from the Naval Academy, and ordered to the Naval Station, Cavite, P. I.

Noble, D. H., asst.-surgeon, detached from duty at the Naval Hospital, Las Animas, Colo., and ordered to the Third Squadron, Pacific Fleet, via the *Maryland*.

Sinclair, J. A. B., asst.-surgeon, detached from the Naval Proving Ground, Indian Head, Md., and granted leave of absence for 2 weeks.

Dunn, H. A., P. A. surgeon, ordered to the Naval Proving Ground, Indian Head, Md., August 23.

Webb, U. R., P. A. surgeon, ordered to duty at the Naval Hospital, Mare Island, Cal., August 24.

Henry, R. B., asst.-*surgeon*, *detached from* the Naval Magazine, Iona Island, N. Y., and ordered to the Third Squadron, of the Pacific Fleet.

Public Health and Marine-Hospital Service

List of changes for the seven days ended Aug. 18, 1909:

Glennan, A. H., asst. surgeon general, leave granted July 17, 1909, for 28 days from July 20, 1909, amended to read 25 days from July 20, 1909.

Stoner, George W., surgeon, granted 11 days' leave of absence from August 17, 1909.

Banks, Charles E., surgeon, granted 5 days' leave en route to station.

Cobb, J. O., surgeon, granted 10 days, leave of absence from Aug. 15, 1909.

Wertenbaker, C. P., surgeon, granted 1 month's leave of absence from Aug. 16, 1909.

Lavinder, C. H., P. A. surgeon, directed to proceed to Peoria, Ill., on special temporary duty.

Parker, Herman B., P. A. surgeon, granted 15 days' leave of absence from Aug. 16, 1909.

Ramus, Carl, P. A. surgeon, granted 1 day's leave of absence, July 11, 1909, under paragraph 191, Service Regulations.

Goldberger, Joseph, P. A. surgeon, granted 1 day's leave of absence en route to station.

McCoy, G. W., P. A. surgeon, directed to make certain inspection trips in Contra Costa and adjacent counties in California on special temporary duty.

Ebersole, R. E., P. A. surgeon, granted 2 months' leave of absence from Aug. 12, 1909.

McKeon, F. H., P. A. *surgeon, granted 4 days' leave of absence* from June 29, 1909, under paragraph 191, Service Regulations.

Chapin, C. W., asst.-surgeon, directed to proceed to Portland, Ore., on special temporary duty.

Bean, L. C., acting asst.-surgeon, granted 5 days' leave of absence from Aug. 15, 1909.

Cross, I. J., acting asst.-surgeon, granted 30 days' leave of absence from Sept. 9, 1909, with pay, and 13 days from Oct. 9, 1909, without pay.

Fabian, J. J., acting asst.-surgeon, granted 6 days' leave of absence from Aug. 2, 1909, under paragraph 210, Service Regulations.

Hamilton, H. J., acting asst.-surgeon, granted 2 days' leave of *absence from* Aug. 16, 1909.

Townsend, W., acting asst.-surgeon, granted 14 days' leave of absence from Aug. 8, 1909.

Walkley, W. S., acting asst.-surgeon, granted 4 days' leave of absence from Aug. 25, 1909.

BOARDS CONVENED

Board of medical officers convened to meet at the Marine Hospital, Baltimore, Aug. 16, 1909, for the purpose of making a physical examination of two officers of the Revenue-Cutter Service. Detail for the board: Surgeon W. P. McIntosh, chairman; P. A. Surgeon M. K. Gwyn, recorder.

Health Reports

The following cases of and deaths from smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service during the week ended Aug. 20, 1909:

SMALLPOX—UNITED STATES

Louisiana: New Orleans, July 31-Aug. 7, 1 case.
Montana: Butte, July 31-Aug. 7, 3 cases.
Oklahoma: Oklahoma City, July 31-Aug. 7, 1 case.

SMALLPOX—FOREIGN

Brazil: Bahia, June 11-25, 6 cases, 1 death; Rio de Janeiro, June 26-July 11, 8 cases, 2 deaths.
China: Amoy, July 3-10, 1 death; Shanghai, June 19-26, 1 case.
Egypt: Cairo, June 24-July, 1 death; Suez, June 18-24, 2 cases, July 1-8, 2 cases.
France: Paris, May 28-June 5, 7 cases, July 17-24, 2 cases.
India: Bombay, June 29-July 6, 4 deaths; Calcutta, June 19-26, 8 deaths; Madras, June 26-July 2, 1 death.
Italy: General, July 18-25, 12 cases; Naples, 39 cases, 5 deaths.
Mexico: Mexico City, July 3-10, 11 deaths; Monterey, July 25-Aug. 1, 1 death.
Portugal: Lisbon, July 24-31, 7 cases.
Russia: Libau, July 18-25, 1 case; Riga, July 11-24, 7 cases; St. Petersburg, July 3-10, 16 cases, 3 deaths; Warsaw, June 5-12, 2 deaths.
Siam: Bangkok, June 1-30, 1 case.
Siberia: Vladivostok, May 27-June 3, 2 cases, 1 death.
Spain: Vigo, July 18-24, 1 case.

YELLOW FEVER

Brazil: Bahia, June 11-25, 9 cases, 5 deaths.
British Guiana: Suddie, July 22, 1 case, 1 death.

CHOLERA—INSULAR

Philippine Islands: Manila, June 19-26, 76 cases, 50 deaths.

CHOLERA—FOREIGN

China: Amoy, July 3-10, 25 deaths.
India: Bombay, June 29-July 6, 12 deaths; Calcutta, June 19-26, 55 deaths; Rangoon, 2 deaths.
Russia: General, exclusive of St. Petersburg, July 23-30, 346 cases, 136 deaths; St. Petersburg, 390 cases, 165 deaths.

PLAGUE

Brazil: Bahia, June 11-25, 8 cases, 5 deaths; Rio de Janeiro, July 4-11, 1 case.
China: Amoy, July 3-10, 79 deaths; Hongkong, June 19-July 3, 7 cases, 7 deaths.
Ecuador: Guayaquil, June-July 10, 3 deaths.
India: General, June 26-July 3, 553 cases, 478 deaths; Bombay, June 29-July 6, 23 deaths; Calcutta, June 19-26, 48 *deaths;* Rangoon, 33 deaths.
Japan: Kobe, July 10-17, 3 cases, 2 deaths.
Siam: Bangkok, June 1-30, 12 cases, 12 deaths.
Venezuela: Caracas, July 17, 2 cases, July 31, 1 case.

Book Notices

Hydrotherapy. A Brief Summary of the Practical Value of Water in Disease. By William H. Dieffenbach, M.D., Professor of Hydrotherapy, New York Homeopathic Medical College and Flower Hospital. Cloth. Pp. 267, with illustrations. Price, $3. New York: Rebman Co.

The first half of this book is devoted to the general principles of hydrotherapy, and to a description, with many excellent photographs, of the apparatus and technic of hydrotherapeutic procedures. The second half is devoted to the practical application of hydrotherapy to diseases. Dr. Dieffenbach is an enthusiastic believer in "the cure of disease by water." In his introduction to the practical part of the book he says: "Although convinced of the almost universality of these applications we do not desire to be classed among those who in their zeal announce hydrothermotherapy as a panacea or cure-all. There are few abnormal conditions where *some* modality of hydrothermo-therapeutics is not called on to do yeoman service. The triumphs of hydrotherapy in fevers, especially in typhoid fever, where hydrotherapy has succeeded in penetrating the citadel of conservatism and of traditional medicine which has hampered the progress of the art of healing for ages are alone sufficient to convince the most skeptical among physicians of the virtues of water in disease." A clean-cut, concise, definite, short yet lucid and comprehensive treatise on this subject is indeed welcome. The present work is all of this—it is written by a master. And yet one can not help but feel that Dr. Dieffenbach in his sincere enthusiasm has materially detracted from the value of his work because of the very "almost universality" that he attributes to hydrotherapeutic procedures. Perfectly satisfied as we are that hydrotherapy has a very wide and very valuable range of usefulness in the art of healing, we are a little skeptical when disease after disease is mustered before us and "*some* modality of hydrothermo-therapeutics" is applied to it, or, as it seems to us at times, even forced on it. It seems to us a far cry from the well-recognized results of hydrotherapy in typhoid to such recommendations as "short cold half baths" with friction as *the* treatment of anemia and chlorosis, with no reference to iron; or to the use of the "iced compress to the vulva, with efficient vaginal packing and mechanical pressure" for the treatment of postpartum hemorrhage, etc. The following quotation in full giving the treatment of membranous croup, will illustrate what has been said:

"This fatal affection requires correct diagnosis, and prompt intervention by the physician. The indications for treatment require clearing the parts of the false membrane, preventing spasms of the glottis and keeping up the resisting power of the child. Moist heat, applied by means of the vapors of the 'croup kettle,' tends to produce local leucocytosis and hyperemia and loosens the membrane. Hot foments applied over the larynx and trachea and changed five times hourly, to be followed by the cold, stimulating compress, will act beneficially. Warm baths, with cold affusions applied every five minutes to the nape of the neck until a vigorous respiratory reaction with cough is induced, have also produced expectoration of the membrane." Such paragraphs, and especially the last sentence, do not appeal to one who has been accustomed to give antitoxin. The book is written from the standpoint of the hydrotherapeutist, as is evident from its substance and also from the titles of the author. Its appeal will be rather to the physician who specializes in institutional hydrotherapeutics, etc., than to the ordinary practitioner of medicine who believes in hydrotherapy as a most valuable adjuvant rather than as a system of therapeutics in itself. The book is nevertheless a valuable and comprehensive summary of the whole subject of hydrotherapy.

Confessions of a Neurasthenic. By William Taylor Marrs, M.D. Cloth. Pp. 114, with illustrations. Price, $1. Philadelphia: F. A. Davis Co.

This interesting bit of satire may serve to arouse some persons who are nursing their own alleged invalidism and may shed light on the conduct of friends who often unwittingly pander to hysteric conditions. If Dr. Marrs has omitted any symptoms in his fanciful portrayal, they fail to occur to us at the present moment.

The Emmanuel Movement in a New England Town. By Lyman P. Powell, Rector of St. John's Church, Northampton, Mass. Cloth. Pp. 194, with illustrations. Price, $1.25. New York: G. P. Putnam's Sons, 1909.

Mr. Powell is one of the leading workers in the so-called Emmanuel movement and may be accepted as one of the expositors of what it claims to accomplish. According to him, "every Emmanuel clinic works within the limitations set by scientific medicine," but he follows this by the statement that "every Emmanuel worker follows his own temperament and training in the application of the principle." Here lies the peril and the basis for the criticisms which have been rather numerous both from physicians and clergymen. There is no question but that a religious stimulus is of great value in many forms of mental and even bodily ailment; a thorough medical education would be of great value to many clergymen and some physicians probably suffer on account of their lack of religious faith and training. The debatable ground, however, between moral and physical healing is full of pitfalls for the injudicious and we fear that anything like a healing cult, such as the Emmanuel movement appears to be developing into, is full of perils to the church as well as to the public welfare generally. Not every clergyman is possessed of proper balance and judgment to go beyond the limits that have usually been set to his functions and the tendency to conscious or unconscious fakerism is likely sooner or later to appear if the practice is to spread. Even with the advice of physicians cooperating with the minister there are dangers. The most fatal form of organic insanity in the active period of life is often indistinguishable in its earlier stages from neurasthenic conditions. Mr. Powell does not seem altogether free from undue credulity. His statement as to the effects of the reading of the twenty-third chapter of Dubois' well-known work seem to us somewhat like evidence of this. His ideas of hypnotism do not appear very well defined, and we are not sure that his methods are not as perilous as other more obviously objectionable ones. His book, therefore, is not altogether a safe one to follow in this regard. What will be the outcome of this Emmanuel movement we are not prophets enough to say; it may do no harm, but it looks to us more perilous to the church than to medicine if it is to be taken up by enthusiastic and more or less credulous clergymen to any very great extent.

Seventh Annual Report of the Director of the Bureau of Science, to the Honorable, the Secretary of the Interior. By Paul C. Freer, Director of the Bureau of Science, for the Year Ending Aug. 1, 1908. Paper. Pp. 79. Manila.

The part of this report of interest to medical men is the space given to the Philippine Medical School. This school is organized with a faculty composed partly of clinical instructors who teach while practicing their profession, partly of men devoting their time exclusively to instruction and research, and of others who belong to the staff of the Bureau of Science, and whose salaries are paid by that bureau. The result is that there is some conflict between the demands made by the school on the one hand and the bureau on the other. The situation is complicated by the fact that the men belonging to the laboratory staff are compelled to give much of their time to clinical work and the organization of the hospital and the school. The report suggests that the government should appoint independent clinical professors who should care for the patients, leaving the laboratory men free to pursue their important investigations. The total number of students in the school is 67. The question of admission requirements is discussed and the fact that the authorities have been quite lenient in applying these requirements is explained by the necessity of providing as soon as possible trained native physicians who will be able to advance the hygienic work in the islands and interpret the requirements of the government to their countrymen with a belief in their necessity. The report emphasizes the necessity of carrying on, in addition to work in Manila, research and practical work in the provinces. For this it is proposed to use the opportunity afforded by the periodic segregation of lepers to be sent to the Culion leper colony. Interesting cases found at these meetings should be brought to Manila for investigation. The other portions of the report are also of considerable interest and show that the worthy standard set by the Philippine Bureau of Science is being maintained.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Iowa: State House, Des Moines, September 21-23. Sec., Dr. Louis A. Thomas.

Missouri: Kansas City, September 20-22. Sec., Dr. J. A. B. Adcock, Warrensburg.

New York: Albany, September 21-24. Chief of Examinations Division, Charles F. Wheelock, Albany.

Massachusetts: State House, Boston, September 14-16. Sec., Dr. Edwin B. Harvey.

The Preparation for the Study of Medicine

An article bearing the above title by Dr. Frederic T. Lewis of Harvard Medical School appears in the *Popular Science Monthly*,[1] and is worthy of careful reading by those having to do with medical education.

Dr. Lewis names subjects which the student during his preliminary college course should take up and gives reasons why they are of importance. The subjects recommended are zoology, botany, chemistry, physics, mathematics, psychology, French and German, English literature and drawing. In zoology, the value of the biologic methods, including dissection and microscopic technic, is emphasized. A table is given based on examinations in anatomy and histology; held by Harvard Medical School for the class which entered in 1907. This table shows that the highest averages were obtained by the students who had previously studied zoology. In botany a study of the morphology of plants with special reference to the fungi is recommended because of the aid it gives in the study of bacteria. The study of flowering plants, however, is not recommended.

The value of the study of chemistry, general and organic, is emphasized because of the aid in the future study of physiology and physiologic chemistry. A college course in physics "with laboratory work consisting of accurate measurements" is recommended as a valuable preparation for the study of physiology and its bearing on numerous problems of medicine. In mathematics, Dr. Lewis shows that plane geometry and plane trigonometry are essential to the securing of the desired preliminary course in physics and that for advanced physics, solid geometry and higher mathematics are needed. A knowledge of psychology is important, particularly in the study of nervous diseases and psychiatry. A half course in psychology, therefore, is recommended.

The reading knowledge of French and German is important in order that the student may benefit from the large number of medical books and periodicals published in those languages and which are invaluable to the student, the practitioner and the investigator. The study of English literature is recommended, not only because of its utilitarian value, but also as a source of recreation and diversion from specialized scientific studies. Drawing is valuable in developing accuracy of observation, since the very act of drawing or modeling an object calls attention to many details otherwise overlooked.

While all this may be secured in two years of collegiate work, it is recommended that students who can possibly do so should take the complete college course before beginning the study of medicine.

South Carolina June Report

Dr. Harry H. Wyman, secretary of the State Board of Medical Examiners, reports the written examination held at Columbia, June 8-10, 1909. The number of subjects examined in was 18; total number of questions asked, 85; percentage required to pass, 75. The total number of candidates examined was 81, of whom 46 passed and 33 failed. One candidate did not complete the examination. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Howard University, Washington	(1909)	79.
Medical College of Georgia	(1909)	75.2, 81.4
Atlanta College of Physicians and Surgeons	(1908)	80.5
University of Maryland	(1907) 85.4; (1908) 75.2, 81.6; (1909)	78.7, 80.2, 82.1, 82.2.
Louisville and Hospital Medical College	(1908)	77.1
Columbia University, College of Phys. and Surg.	(1906)	81.5
North Carolina Medical College	(1909)	76.2, 83.9
Jefferson Medical College	(1908)	84.2
Medical College of the State of South Carolina	(1909)	75, 75, 75, 75.5, 75.6, 75.7, 75.7, 76.9, 78.6, 78.9, 79.4, 80, 80.6, 80.9, 81.5, 82, 82, 82.4, 83.2, 83.9, 84.2, 84.7, 84.9, 87.2.
Meharry Medical College	(1908) 75; (1909)	79.1
Vanderbilt University	(1909)	76.1
University of Nashville	(1909)	75, 81.6
Medical College of Virginia	(1908)	90.9

Marriages

R. P. Cowles, M.D., to Miss Sarah C. McConville, at Baltimore, August 6.

Otto Fisher, M.D., Trenton, N. J., to Miss Mollie Nash, at Reisterstown, Md., August 14.

Henry Strong Denison, M.D., to Miss Jeannette Welch, both of New London, Conn., August 19.

Giuseppe Previtali, M.D., New York City, to Miss Rose R. Morrow, at Windsor Hills, Md., August 8.

Swithin Chandler, M.D., Philadelphia, Pa., to Miss Elizabeth Dickenson of Middletown, Conn., July 31.

Daniel B. Redmond, M.D. to Miss Eva Fewell, both of Washington, D. C., at Rockville, Md., August 11.

Anthony Gruessner, M.D., New Brunswick, N. J., to Miss Piozsika Deutsch, of New York City, August 14.

Deaths

Walter Gilman Curtis, M.D. Harvard Medical School, Boston, 1846; acting assistant surgeon in the Army before the Civil War, and medical quarantine officer of the Cape Fear river thereafter; state quarantine physician for nearly 30 years; in 1868 clerk of the superior court of Brunswick county, N. C.; and for many years a magistrate and member of the board of county commissioners; died at his home in Southport, N. C., August 8, aged 83.

Henry G. Christzman, M.D. Pennsylvania Medical College, Gettysburg, 1859; surgeon in the Army during the Civil War, and in charge of the Hagerstown (Md.) Hospital during and after the battle of Antietam; for many years a U. S. pension examining surgeon at Washington; ex-president and an honorary member of the Medical Society of Franklin County; died at his home in Welsh Run, Pa., August 10, from paralysis, aged 72.

Byron Clark, M.D. University of Maryland, Baltimore, 1881, College of Physicians and Surgeons, Baltimore, 1881; formerly professor of theory and practice of medicine in the Eclectic Medical College of the City of New York; died at his home in Washington, Pa., August 5, from diabetes, aged 72.

William Smith, M.D. Cleveland Medical College, 1848; Columbus Medical College, 1876; a veteran of the Mexican and Civil Wars; and for many years a member of the American Medical Association; died at his home in Van Wert, Ohio, August 8, from heat exhaustion, aged 87.

James P. Rorex, M.D. University of Alabama, Mobile, 1875; died at his home in Scottsboro, Ala., August 8, from a gunshot wound of the heart, supposedly self-inflicted, while despondent on account of ill-health, aged 64.

John Jacob Beyer, M.D. Jefferson Medical College, Philadelphia, 1890; a member of the Medical Society of the State of Pennsylvania; died at his home in Philadelphia, August 9, from locomotor ataxia, aged 51.

Louis Jacob Eger, M.D. Starling Medical College, Columbus, Ohio, 1893; a specialist on diseases of the eye, ear, nose and throat; died at his home in Delphos, Ohio, August 4, from cerebral meningitis, aged 41.

William Forrester, M.D. University of Louisville (Ky.), 1862; surgeon of the Fifth Kentucky Volunteer Cavalry during the Civil War; died in Louisville, August 15, aged 72.

---

[1] July, 1909, p. 65

Stanley Theodore Boggess, M.D. Bellevue Hospital Medical College, New York City, 1891; of Bristol, W. Va.; died in a hospital in Clarksburg, W. Va., August 5, from tetanus, aged 47.

Pleasant James Monroe Burket, M.D. University of Michigan, Ann Arbor, 1865; a veteran of the Civil War; died at his home in Topeka, Kan., July 3, from heart disease, aged 65.

Marcellus M. Adams, M.D. Medical College of Indiana, Indianapolis, 1885; a member of the Indiana State Medical Association; died at his home in Greenfield, August 5, aged 75.

Kent Black, M.D. Medical College of Virginia, Richmond, 1878; a member of the Medical Society of Virginia; died suddenly on his farm near Blacksburg, Va., August 12, aged 53.

William R. Wall, M.D. Homeopathic Hospital College, Cleveland, Ohio, 1887; died suddenly at his home in Willoughby, Ohio, August 7, from cerebral hemorrhage, aged 68.

James C. Harrington, M.D. Cleveland University of Medicine and Surgery, 1865; of Brooklyn, N. Y.; died at the home of his daughter in Bellevue, Pa., July 15, aged 72.

Emanuel A. Smith, M.D. Medical College of Indiana, Indianapolis, 1892; of Newton Stewart, Ind.; died at the home of his brother in Bird's Eye, Ind., July 9, aged 62.

George Washington Hamill, M.D. Bellevue Hospital Medical College, New York City, 1876; of Baltimore, Md.; died at Mercy Hospital in that city, August 13, aged 56.

Samuel W. Yearick (license, Iowa, 1885); an eclectic practitioner of Cedar Rapids; and a veteran of the Civil War; died at his home, July 18, aged 74.

Michael C. Kett, M.D. University of Georgetown, D. C., 1904; of Glenwood Springs, Colo.; was killed August 6, in a runaway accident at that place, aged 30.

Robert Emmett Jones, M.D. Western Reserve University, Cleveland, 1884; died at his home in Bethany, W. Va., August 2, from anemia, aged 59.

John Davis Thornton, M.D. University of Kansas City, Mo., 1887; of Des Moines, Iowa; died in Kansas City, August 2, from brain disease, aged 56.

Marion M. Erwin (license, Ark., 1903); a Confederate veteran, died at his home in Newport, Ark., August, 2, from pneumonia, aged 59.

Thomas Charles Stevenson, M.D. Western Pennsylvania Medical College, Pittsburg, 1893; died at his home in Carnegie, Pa., August 6, aged 42.

Edward Cornet, M.D. National University of Illinois, Chicago, 1892; died at his home in Uncasville, Conn., from paralysis, aged 62.

George W. Baker, an eclectic practitioner of Leon, Iowa; died at his home January 10, from pneumonia, aged 87.

Thomas D. Hulme (license, practitioner, Iowa, 1886); died at his home near Commerce, Iowa, August 8, aged 68.

Medical and Chirurgical Faculty of Maryland Establishes a Permanent Relief Fund

The July number of the *Bulletin of the Medical and Chirurgical Faculty of Maryland* contains the report of the committee on a fund for the relief of widows and orphans of deceased members, showing the work which has been accomplished during the past year. This fund, established in 1903, has been steadily growing and has recently been considerably enlarged through the organization of the Ladies' Auxiliary. Dr. Eugene F. Cordell, the chairman of the committee, gives the following account of its establishment and activities:

> Several times in the long life of the Faculty, extending back to the eighteenth century, the matter was discussed and at different times resolutions adopted, to carry the plan into execution, but it was not until 1903 that it was successful. At the annual meeting of the Faculty, held in Baltimore in April of that year, a resolution was adopted founding a permanent fund for the relief of the widows and orphans of deceased members. This fund was placed in the hands of the committee to invest and to use the annual interest for the relief of those who might be in need of it. Personal effort was needed to make the project a success. Solicitation among friends and members of the profession secured several hundred dollars within the first year. While the fund has not increased as rapidly as it should, it is growing and is safely invested in 5 per cent. bonds. The goal which the committee has in view is the securing of an amount which will yield an annual income of at least $1,000. There is little doubt that before long, as the charity becomes known and appreciated, gifts and bequests will come in which will make its work an important part of the activities of the Faculty. It is the hope of the committee to establish somewhere near Baltimore a home for the widows and orphans of physicians, where they can be cared for and where the children can be educated. It seemed to the committee that if the women of the Faculty, the wives, sisters, mothers and daughters of the 1,100 members, could be interested in this work, it would be prosecuted with greater success. The recent dedication of the fine new building of the Faculty offered an opportunity to carry this idea into execution. The brilliant opening of May 13-15 drew the community and especially the ladies together, and made them see what a powerful body the medical profession was under its new organization. The local newspapers were full of our career and work and the project was well advertised as a result. Accordingly, a Ladies' Auxiliary of the Widows and Orphans Fund was organized, making the women, in a measure, members of the Faculty. They entered on their work with enthusiasm, a large membership committee having been appointed to secure the membership of all the ladies. In October, an entertainment will be held in Osler Hall, at which reports of the work of the Ladies' Auxilary will be made. A large number of the wives and daughters of members of the Faculty are taking an interest in the plan. It is hoped that eventually a permanent home may be established, which will offer its hospitality not only to the widows and orphans of physicians, but also to the superannuated physicians themselves.

The work outlined above is most commendable, and the result in Maryland will be watched with interest. State associations can well give such a plan careful consideration in selecting possible lines of development.

Society Proceedings

COMING MEETINGS

Amer. Assn. Obstetricians and Gynecologists, Ft. Wayne, Ind., Sept. 2.
Amer. Electrotherapeutic Association, New York, September 14-16.
Colorado State Medical Association, Estes Park, September 19.
Michigan State Medical Society, Kalamazoo, September 15-16.
Missouri Valley, Med. Society of, Council Bluffs, Ia., September 9-10.
New Mexico Medical Society, Roswell, September 15-16.

Wyoming State Medical Society, Cheyenne, September 1-2.

OREGON STATE MEDICAL ASSOCIATION

Annual Meeting held at Seattle, July 20-23, 1909

The President, DR. W. H. BYRD, in the Chair

The officers elected were named in THE JOURNAL, Aug. 7, 1909, p. 467.

The report of the secretary showed a membership of 371. This included one new society, the Polk-Yamhill, of which Dr. W. G. Gilstrap is president and Dr. L. A. Bollman, secretary. The state association granted a charter to this society.

Practice Act Discussed

The Committee on Public Policy and Legislation endorsed a plan for the consideration of a practice act, as a special order of business for the next meeting. The model bill presented in the state legislature at the last session had been defeated, and it was with a view to passing this that the motion was made. The bill was widely discussed at the meeting.

Ophthalmia Neonatorum

DR. J. F. DICKSON, the Oregon representative of the committee on Ophthalmia Neonatorum of the American Medical Association, urged the appointment of a special committee of three to secure the passage of a bill regulating the practice of physicians and midwives in the care of new-born infants. The matter was referred to the Committee on Public Policy and Legislation, who will be urged to adopt the plan.

Official Journal Considered

The important business of the session was the adoption of an official journal. The Committee on Journal, Drs. W. T. Williamson, C. J. Smith and K. A. J. Mackenzie, appointed last year to consider the best methods of publication, endorsed a plan for the formation of a Northwest Publishing Association and presented articles of incorporation, constitution and by-laws. *Northwest Medicine*, published at Seattle, and for several years official journal of the Washington State Medical Association, had offered to lease its plant to the states entering into the agreement, and it was recommended that this journal be made the official organ of the states of the Pacific Northwest. According to the plan recommended each state medical association will elect three trustees, and the trustees from all the states will elect an editor-in-chief and managing editor, forming a publishing company to be known as the "Pacific Northwest Publishing Association." Each state will have two associate editors and the state secretaries will become assistant editors *ex-officio*.

The journal will continue to be known as *Northwest Medicine*, and will be furnished to each member by the state associations. As at present arranged, the new publication will prove a most desirable one. The Oregon State Medical Association adopted the plan, as did also the Washington State Medical Association. Idaho is expected to do likewise, and it is hoped that British Columbia willl join in the plan. Much satisfaction is being expressed by physicians of the Northwest, who thoroughly approve the arrangement, which will go into effect immediately.

Report of Delegate to American Medical Association

The delegate to the American Medical Association, Dr. A. C. Smith, reported the results of his observations while attending the last meeting of the American Medical Association. He made a motion that the next delegate from the Oregon State Medical Association be instructed to promote legislation tending to carry out the suggestions of President Burrell advising the segregation of the three offices of secretaryship, managership and editorship of The Journal of the American Medical Association, and that he also be instructed to initiate or support any action tending toward the restriction of the term of office of the members of the Board of Trustees to one term. This motion was carried.

Northwest District Association Formed

The chairman appointed a committee of three, Drs. N. Moliter, La Grande, W. G. Gilstrap, Sheridan, and W. T. Williamson, Portland, to consider the advisability of forming a northwest association comprising Oregon, Washington, British Columbia and Idaho. The project was favorably reported and organization effected (as already noted in The Journal).

The three journal trustee nominees, Drs. W. T. Williamson, C. J. Smith and K. A. J. MacKenzie, were elected unanimously to serve in order named for one, two and three years respectively.

The next place of meeting will be Portland, Oregon, in 1910.

NEW JERSEY STATE MEDICAL SOCIETY

Annual Meeting held at Cape May, June 23-25, 1909

(Concluded from page 650)

Medical Expert Testimony

Dr. T. P. Prout, Summit, protested against the present methods of judicial procedure, and said that unless one's knowledge dated from the seventeenth century, one was of very little importance in a court of law. The venerable question always propounded whenever insanity was in question ignored completely the advances that had taken place in two centuries of medical practice. The slow administration of justice was a characteristic of bad civilization; for it meant a costly administration. He did not consider our penal system adapted to cure criminals, who were always abnormal. He hoped that the day might come when an improvement would be made in the present legal system, and the prison would become the laboratory of an active science of jurisprudence. He stated that any three physicians who had had training in a certain department would be able to come to an agreement, provided they had access to all the facts, and suggested a plan by which the medical experts should be appointed in such a way as not to be bound to testify in favor of one side or the other.

DISCUSSION

Dr. Britton D. Evans, Graystone Park, said that medical experts could not be criticised for not always being harmonious, as the eminent men who had just spoken on the subject of obstetrics did not seem to be by any means altogether agreed. He stated that the objection to changing the system of employing medical expert witnesses was that the Constitution of the United States guaranteed to an accused citizen the right to summon experts from anywhere who would tend to help his cause. Men appointed as experts with a life tenure would not always agree. That a life tenure did not insure agreement had been shown by the Dred Scott decision.

Dr. E. Ill thought that when the day came that there would be no difference of opinion among physicians, there would be no physical body. He said that Dr. Prout's paper should be widely circulated among medical men, so that honest members of the profession might endeavor to have revised this cumbersome machinery of the law. He believed that if the asking of hypothetical questions could be abolished, this would constitute a long step in the right direction. He stated that no countries except Great Britain and the United States allow witnesses to be insulted by the attorneys without rebuke.

Pathognomonic Signs Relating to Appendix Localization

Dr. A. J. Walschied, Union Hill, stated that besides pain, muscular rigidity, tenderness, tumor, etc., there were a number of signs that, if carefully studied, could localize the appendix, its direction and, in a great many instances, its pathologic state and prognosis. He considered the normal position of the appendix, and how it could be placed in these various positions. The positions of the appendix, he said, were: (1) the intrapelvic, with the development of the bladder, rectal, and uterine adnexa symptoms; (2) near the iliopsoas muscles, producing leg symptoms; (3) the position upward, outward, and backward, producing lumbar pains in chronic cases; and (4) upward and inward, or under the liver, producing respiratory symptoms. He touched on the importance of pain in relation to localization, particularly in outward and upward locations, or in inward, pointing toward the median line. Tenderness, as an important factor in localization, was also referred to; as well as the significance of McBurney's point, in making a fine diagnosis of the position and condition of the appendix. The importance of gastrointestinal disturbances was next described. Pain and tenderness he considered of value in showing the degree of inflammation.

DISCUSSION

Dr. George W. J. Sommers, Trenton, said that the diagnosis in most cases depended on the position occupied by the appendix. Those in which the tip pointed toward the other side of the colon were favorable for operation; while those in which it turned inward were more serious. He considered a study of the blood count an aid in the diagnosis of appendicitis, particularly a differential leucocyte count. He thought that the patients should be operated on as soon as the diagnosis was made, and considered a dose of castor oil a very good temporary expedient in cases of doubt. He believed, also, in the starvation plan of treatment in so-called inoperative cases. He had seen patients thus treated live long enough to be operated on successfully at a subsequent time.

Dr. Theodore Senseman, Atlantic City, did not believe the location of the direction in which the appendix pointed to be of any practical value. He thought that the first twenty-four hours in an appendix case would be better consumed in getting the patient ready to be operated on than in taking a leucocyte count. If one found the base of the appendix, it was easy enough to reach the tip.

Dr. J. M. Rector, Jersey City, referred to cases in which the appendix is sympathetically connected with the uterine adnexa, primary inflammatory changes in one of these being associated with secondary inflammatory changes in the other.

Dr. Walschied said that it was difficult sometimes to convince people of the necessity of early operation in appendicitis; and that in such cases one could wait and see whether, at the end of twenty-four hours, the acute pain was still present, meanwhile making the blood count and giving large doses of castor oil. While he admitted that the location of the tip of the appendix was not important to the general practitioner, he thought it very advantageous for the surgeon to know it.

Sterilization of Confirmed Criminals, Idiots, and Other Defectives by Vasectomy

Dr. William J. Chandler, South Orange, said that students in sociology had called attention to the fact that the birth rate of the criminal and defective classes was increasing much more rapidly than that of intelligent and law-abiding citizens. This was probably because these defectives had no sense of responsibility, and sought only the gratification of their animal natures. He referred to the famous Jukes family of criminals, prostitutes, vagabonds and paupers, to support the view that crime was hereditary. Society had sought to protect itself against the increasing number of criminals and defectives by passing punitive laws and by maintaining institutions for such persons. This had entailed considerable expense on the community, and had not been particularly successful. Some states had forbidden the marriage of persons who were epileptic, imbecile, feeble-minded, or afflicted with insanity; but, unfortunately, the race could be propagated without marriage. Segregation or colonization was costly, and deprived many otherwise useful citizens of their liberty. Castration unsexed the individual; and, while advisable as an additional punishment for a limited number of criminals, was objectionable as a general measure. Vasectomy, however, was simple, safe, and thoroughly efficient. It would prevent propagation without unsexing the individual. Dr. Harry C. Sharp, of Indianapolis, for a long time chief physician of the Indiana State Reformatory, had done many hundreds of these operations, and stated that it in no manner limits the marital relations, except in the prevention of procreation. Indiana and several other states have passed laws making it compulsory for unimprovable defectives to submit to this operation.

DISCUSSION

Dr. Chandler offered a resolution that a committee be named to prepare a bill on the lines of the Indiana law, and to present it at the next meeting of the Legislature.

Dr. George H. Balleray, Paterson, said that we were what we were in consequence of heredity and environment. Therefore, the propagation of the human race should not be left entirely to chance. In the breeding of the lower animals, great precautions were taken to improve the stock and to prevent crossing with inferior animals. This was not so with humanity, and the result was often a progeny that was a disgrace. One of the measures that Dr. Balleray thought would be beneficial in this respect was the control of immigration. There were laws in existence supposed to do this, but they were not enforced. Dr. Balleray said that at present there were no especial means of preventing the marriage of the unfit. He thought that a law regulating this should be passed in every state, and that the applicant for matrimony should be made to pass an examination as severe as that required now of an applicant for life insurance. He thought that it should not be vasectomy, but castration that should be performed.

Dr. Prout said that the procedure should be undertaken with some trepidation, because not much was yet known concerning the ultimate effects of vasectomy. He thought that the performance of the operation on criminals would place them in a position of absolute irresponsibility; and that to allow them their liberty would cause a good deal of trouble.

Dr. D. E. English thought that the criminals were about as irresponsible now as they could be. He was not in favor of the operation for females, as it is more serious in them than in males. He believed that very few prostitutes had children.

Dr. Cornell did not think that the law in Kansas prohibiting the marriage of degenerate and unfit persons could have a fair trial until other surrounding states passed similar laws; as people who wished to be married needed only to step across the border. He said that the fact that some criminals had stated that they felt better after the operation of vasectomy did not prove it to be a good thing. He considered that the results given by Dr. Chandler lacked the accuracy of scientific verification.

Dr. D. C. English made a motion that a special committee, consisting of Drs. Chandler, Balleray and Prout, be appointed, and that the recommendation contained in Dr. Chandler's paper be referred to this committee with power to prepare a bill and have it introduced at the next session of the Legislature. His motion was seconded and carried; and the committee was appointed. He did not think that the procedure should be regarded entirely as a punitive measure, as many of these persons were not criminals. If they could be put into a safer and better condition by vasectomy, he thought it was well to employ it. These people were not more irresponsible after the operation than before, and were better able to restrain themselves. No harm had been observed in either women or men as the result of the operation.

Dr. Balleray was willing that vasectomy should be performed on the feeble-minded, but felt that to remove the testicles of criminals would have a great deterrent effect.

Dr. Chandler said that he had recommended castration for a certain class of criminals.

Mental Hygiene and Prophylaxis

Dr. Henry A. Cotton, Trenton, reviewed the recent advances in the study of psychiatry and in the care and treatment of patients in insane hospitals, and said that not only in prophylaxis, but also in the after-treatment of patients who leave the hospital, the physician had an important field. There were a great many preventable forms of insanity, alcoholics making 20 per cent. of the admissions and 10 per cent. more being cases of general paralysis due to syphilis. These, with other indirect causes of insanity, would run the estimate up to 50 per cent. of cases of insanity that were entirely preventable. He regretted that the New Jersey law did not provide for voluntary commitment, and hoped that this defect would be remedied at the next session of the legislature. He thought that the care of the acute insane should not be entrusted to a layman, no matter how good. He believed that the counsel of the family physician would often be of value in so directing the life of his patient as to prevent the development of insanity.

Dr. Prout emphasized the upbringing of children as an element in the prophylaxis. He thought that obedience and imagination were both parts of the character sadly neglected in the training of children in the United States. This he considered a serious defect, and one that would lay the foundation for an unstable equilibrium in the mind of the individual.

Dr. Alexander Marcy, Jr., Riverton, thought that institutions for the insane should be under the care of men thoroughly trained in this particular specialty. He thought that Dr. Cotton would not have gone far wrong if he had said that 75 per cent. of the cases of insanity are directly due to alcohol. He believed in a sharp differentation between the acute and curable insane and the chronic and incurable. He thought that the county institutions should take care of the latter, but that the state should take charge of the former, separating them from the chronic cases. He thought that the acute cases needed the most careful, painstaking, and thorough investigation. He believed that the stigmata of insanity were often implanted in the offspring of the degenerate, and considered the two questions closely allied.

Dr. Parsons said that the county asylum did care for the acute cases; and that chronic cases required much more care than the acute. He thought Dr. Marcy was discriminating too much in favor of one class at the expense of the other.

Dr. Luther M. Halsey, Williamstown, said that at the present day institutions for the insane were no longer regarded as asylums, but were looked on as hospitals. Daily staff consultations were held, and the management of the different cases discussed. He thought it almost impossible to get a lay superintendent capable of managing a county insane institution properly, and thought that politics was very likely to creep into the matter. He was in favor of a closer relation between the hospital physician and the general practitioner.

Dr. Cotton did not think that every patient who had been in the state hospital for five years should be sent back to the county institution, as in a good many chronic cases the patients were violent and hard to manage. When they reached a stage of quiet dementia, they could be taught farming and housework. He thought that the physicians in county asylums worked under a great disadvantage, as they could not always get the superintendent to do what they wished.

The Supernutritive Properties of Milk

Dr. Alexander McAlister, Camden, said that cows' milk was ideal only for calves, although there was less danger in feeding a child with cows' milk than with that of any other animals. The fetus was nourished before birth by the blood, and afterward by milk, which was the nearest thing to blood. Milk was now regarded as a collection of living cells suspended in serum. These cells were nearly related to the white blood corpuscles. The valuable supernutritive properties were found only in whole milk. Milk that was not definitely known to be good and new should not be endorsed by physicians for nursery and clinical use. It was almost always possible in this country to get milk containing 100 per cent. of economic goodness. The place that could not command good milk for its infants and invalids should be held up to ridicule.

At What Age should a Child be Admitted to our Public Schools?

Dr. Joseph Funk, Elizabeth, said that the law of New Jersey permitted children to be sent to school at the age of 5 years. He considered this far too young, as mental development could not be expected until the child had laid the foundation for a good physical development. At 5, they were too young to concentrate their minds, and even tired of play very quickly. He thought no child should be sent to school until 7 years old, and that during the first two years after this the school hours should be short. A great deal of the school time should be spent in the open air.

DISCUSSION

Dr. Marcy said that he wished to emphasize the points of shortening the school year, limiting the hours of confinement, attending more thoroughly to the physical and moral development, and allowing the mental development largely to take care of itself.

Dr. Elias J. Marsh, Paterson, said that classes often had to be put on half time because school accommodations were insufficient. He suggested that the financial problem could be solved by having the children spend a large part of their time out of doors during school hours, using the ground around school houses for the purpose of conducting their exercises in for part of the day.

Dr. Henry L. Coit, Newark, considered it a mistake to send a child to school before the age of 8, the period between 5 and 8 being that of most critical development for the nervous system and in which it gained its greatest strength.

Dr. Livengood said that there were too many studies in the public schools, and that the subjects were often too abstruse for the minds of the children. Even if the school hours were shorter, it would take all the pupils' spare time to prepare lessons. If the schools could be taken out of politics, he thought that radical changes in the right direction could be made.

Dr. Chavanne did not approve of the manner in which children were stuffed with information, and said that much of the knowledge thus acquired was of no subsequent use.

Dr. Linn Emerson, Orange, said that children would readily acquire, in a short time, and without much waste of energy, what it would have required tremendous efforts on the part of the teachers to pound into their heads between the ages of 5 and 7. He thought that the child who began to go to school at the age of 8 years would be better grounded at the age of 12 than the child who had gone to school since the age of 5.

Dr. Cornell said that the teachers were powerless to change the course, unless backed up by the medical profession. They had to be governed by those higher in authority. He thought that if the New Jersey Medical Society would take some action regarding the matter, other state societies would follow its lead.

Dr. Marcy offered a resolution that a committee of three be appointed to consider the subject of the school life of children, to report at the next meeting of the New Jersey Medical Society, and to make monthly reports of progress in the journal of the Society. The motion was seconded and carried.

Points in Infant Feeding

Dr. D. E. English, Milburn, was the author of this paper; but, he having been called home, the paper was read by Dr. D. C. English.

Efforts should be directed, not to making a perfect imitation of mothers' milk, but to obtain a food that suits the infant. No exact rules as to quantity can be laid down. Rules are based on the supposed capacity of the infant's stomach at different ages, and this is a most uncertain and variable criterion. If the child shows a normal increase in length and weight, it must be getting a proper amount of food. Lack of this increase is more often due to the quality than to the quantity of the food. In hot weather, one should be content if the child keeps well, and not insist on an increase in weight and length up to the full amount. The child requires a larger quantity of cows' milk than of breast milk. It is wrong to wake a child and insist on its swallowing a certain amount of food at a particular time. An infant should never be fed when it is not hungry. The child should be allowed to worry a while before each feeding. Occasional crying is the only form of physical exercise that a young infant can get. One should try to make the baby continue feeding until its stomach is full and distended. It is this distention that develops the stomach. It will not produce dilation, which is caused by feeding the child too frequently and not allowing the stomach to become entirely empty. After feeding, the baby should sleep. In regulating the time of feeding, one should not pay attention to the clock, but should watch the baby. The intervals will then tend to approximate those given in the text-books, but will be more irregular. By the age of 18 or 20 months, the feedings can be reduced to three good meals a day with something in between meals.

DISCUSSION

Dr. Francis E. Todd, Paterson, believed in putting the normal baby with a normal mother on the breast as soon as convenient after delivery. He was accustomed to allow the infant to nurse every six hours in the interval between delivery and that of free lactation. He considered the first secretions from the breast necessary to the child, clearing out its intestinal tract and leaving it in condition to take the pure milk of lactation. He thought the child could get almost enough water from the breast, but said that any water given it should be sterile. He preferred to have this given after nursing, instead of before. Breast-fed babies require less attention to their mouths than do bottle-fed babies. He thought that regular nursing brought about regular habits and made the child easier to care for. In mixed feeding, he would allow the child to get all the milk it could from the breast before giving it the bottle. Strong efforts should be made to secure certified or pure milk. He doubted whether the removal of a little of the cream from the top of the bottle would remove enough bacteria to make the procedure worth while. He thought that Dr. English gave the fruit juices a little earlier than necessary, and said that six or seven months was early enough for this. He thought milk formulas too weak, as a rule.

Dr. Livengood said that the child's toys should be sterilized; and that, when placed on the floor, a sterile sheet should be put over the carpet.

Ophthalmia Neonatorum

Dr. T. R. Pagnelli, Hoboken, divided the disease into two forms, gonorrheal and non-gonorrheal, and said that the prognosis was better in the latter than in the former, but that the treatment was similar. Infection usually took place just before or just after the head passed the vagina. If the disease developed later than the fifth day, the disease must have been contracted from outside sources. The diagnosis should present no great difficulty. The prognosis depended on the bacterial cause, the size of the fissure, the stage of the disease, and the nutrition of the infant. Various silver preparations were used in the treatment, and several different acids. The best method was that of Credé, which consists in instilling a drop or two of silver nitrate into the eyes of the new-born child after the lids have been cleaned.

DISCUSSION

Dr. Norton L. Wilson, Elizabeth, had seen far fewer cases in the last eight years than formerly, and believed this to be due to the use of the Credé method of treatment, particularly in institutions. He did not, however, recommend that this method should be employed in every case in private practice. He thought that in non-specific cases the eyes would get well in most instances, whether any treatment were employed or not, provided they were kept clean. Even specific cases would do much better if the eye were frequently and thoroughly flushed. He did not favor the application of continuous cold to the eyes, as he had seen much harm result from it. He preferred nitrate of silver to either argyrol or protargol.

Dr. Emerson's experience with argyrol and protargol had been more satisfactory than that of Dr. Wilson. He believed that in many cases physicians were not explicit enough in giving directions about cleaning the eyes at certain intervals. They should give a demonstration to the one having charge of this of the manner in which it was to be done. He preferred to give a weaker solution to the mother or nurse to instil, and to use the stronger nitrate of silver himself.

Dr. Pagnelli said that if the patient were under the constant observation of the physician, the latter would be pretty well guided regarding any complications arising in the case.

Report on Recent Milk-Commission Legislation

Dr. Henry L. Coit, Newark, said that he was a member of a committee appointed twenty years ago, and never discharged, to attend to the subject of obtaining pure milk. This was the pioneer step in this direction. He said that an act had been passed by the New Jersey Legislature of 1909 conferring on the milk commission a legal status, and that it was the most comprehensive law on the subject ever placed on the statute books.

It was moved, seconded, and carried that the report be received, and that the committee be discharged with the usual pension of thanks of the society.

Medicolegal

Validity of Claims of Physicians for Making an Autopsy

The Supreme Court of Arkansas says, in Clay County vs. Thornton and another, that the latter parties, two physicians, filed claims of $25 each for professional services rendered in making an autopsy at the direction of a justice of the peace, acting in the absence of the regular coroner, who resided more than twenty miles from the place where the death of the subject occurred. On behalf of the county it was said, in opposition to the claims, that the jurors were not sworn in the immediate presence of the dead body, as is contemplated by the Arkansas statute, and that they did not together view the dead body before holding the inquest, as provided by the law, and because of the failure of the acting coroner to comply with the literal terms of the statute in this respect it was contended that the allowance to the physicians for making the autopsy was not valid. But the court does not agree with that. As it views it, this was a matter of procedure that addressed itself to the acting coroner and did not render an act done by the physician in good faith under the direction of the acting coroner unlawful.

It was also contended that the acting coroner exceeded his powers in employing and directing more than one physician to make the autopsy, and that, on that account, the county was not liable. The presiding judge, however, found from the evidence that the services of the two physicians were necessary to ascertain whether the circumstances of the death of the young woman indicated that she had been foully dealt with, and that the fees charged were reasonable. This being so, and the findings and judgment of the lower court, allowing the claims, being sustained by evidence legally sufficient, the supreme court affirms that judgment in the physicians' favor.

What Physicians May and May Not Testify to Involving Range of Bullets

The Criminal Court of Appeals of Oklahoma says, in Price vs. United States, that it was entirely proper for a physician to describe fully the location, character, and range of a bullet wound. But it was error, the court holds, to allow physicians to testify to their opinions as experts as to the position of the arm of the person shot at the time he received the fatal wound based on the range of the bullet after it entered his body. Medical science does not undertake to decide what range a bullet, fired from a gun or pistol, will take after coming in contact with, or entering, the human body. The reports of army surgeons and of army hospitals prove that there is no rule on this subject. They present the most astonishing, contradictory, and apparently impossible results. Therefore it has been uniformly held by the courts that this is not a proper subject for expert evidence. From this it necessarily follows that a physician should not be permitted to testify as an expert to the position of the body of a person when a wound was received, based on the range of the bullet after it entered his body.

Privilege in Case of Communications Made in Presence of Third Persons

The Appellate Court of Indiana, Division No. 1, says, in Indiana Union Traction Co. vs. Thomas, a personal injury case brought by the latter party, that the plaintiff testified as a witness in her own behalf and in the course of her examination in chief testified to services rendered to her immediately after the injury by a certain physician. On her cross-examination it was sought to ask her whether, on the day of the injury, she made certain statements descriptive of the manner in which the injury occurred, to her said physician, at the residence of, and in the presence of, her daughter, and in the presence of another woman. Objections to these questions were properly sustained. The statements about which the inquiries were made were in the nature of privileged communications to a physician within the intent of the Indiana statute. Without the consent of the patient the physician could not testify to such statements made by the patient, and the patient herself could not be compelled to divulge communications between her and her physician. The privilege attaches, notwithstanding the presence of third persons: and, while as to such a communication made in the presence of others, and such other persons be not necessary to enable the patient and the physician to communicate with each other, such third persons may be admitted to testify concerning the communcation, yet the privilege still exists so far as to exclude the testimony of the physician, and the patient as well, from divulging such communication as a witness.

1. **Urethral Affections.**—Beck reviews his experience in those cases of urethral malformations, defects, deformities and injuries, which he has treated by urethral distention within the last nine years. So far as failures of the distention method are concerned, it seems to Beck that they are more due to the hand than to the method itself. The most frequent mistake made is that the urethra is not sufficiently mobilized. The method has yielded extremely gratifying results in Beck's work.

2. **Sphenopalatine Ganglion.**—Meckel's ganglion is in quite as close relation to the nose and its accessory sinuses as is the optic nerve. It has long been recognized that inflammatory processes in the sphenoidal, postethmoidal and maxillary sinuses extend to the optic nerve, and the fact has been demonstrated postmortem (Birsch-Hirschfeld). It is therefore altogether reasonable to assume, Sluder says, that these processes also pass over to Meckel's ganglion, although the clinical picture is very much less striking than the blindness produced by involvement of the optic nerve. According to his observations, characteristic disturbances have followed postethmoidal and sphenoidal suppurative inflammations which can not be explained otherwise than by assuming that Meckel's ganglion has become involved by extension; some of these disturbances have been transitory, and some have persisted for many years. In other cases the conviction has been equally positive that the extension has been from the nose proper. Thus far he has not seen anything that could be interpreted as an extension from the maxillary sinus. From the anatomic relations of Meckel's ganglion to the anterior boundary of the pterygopalatine fossa, i. e., to the posterior wall of the maxillary sinus, it is not very likely to be involved by extension of an inflammatory process from that sinus, inasmuch as the arteria palatina descendens and the arteria sphenopalatina, together with their accompanying veins and the surrounding connective tissue, lie between the ganglion behind, and the wall of the maxillary sinus in front. This relation appears to be constant; and Sluder believes that it explains why clinical manifestations referable to the ganglion do not ordinarily follow inflammatory processes in the maxillary sinus.

3. **Rectal Irrigation.**—Kemp employs a vacuum bottle with a specially devised attachment. Through the screw cap which closes the bottle, passes a small hard rubber (non-heat-conducting tube), to which is attached the outflow tube. Parallel to this is a filiform tube which allows the entrance of a fine column of air so as to render the flow possible. This last tube passes through the solution to within about one-eighth of an inch from the bottom of the bottle. As the instrument is employed inverted, it would correspond to the same distance from the top of the bottle. This filiform tube is of hard rubber externally where exposed to the air as a non-conductor of heat. The part lying within the bottle is purposely made of metal so that it is rapidly heated by the surrounding solution and the entering air is thus in turn heated markedly. A series of experiments demonstrated that there is only a loss of from 1 to 2 F. in the temperature of the solution in the bottle during the administration of proctoclysis (the drop method) lasting half an hour, a negligible amount. A screw compression valve is applied close to the bottle attachment so as to avoid as much as possible the solution cooling in the soft outflow tube. This outflow tube is joined to the catheter by a short piece of glass tubing for the purpose of observing whether the flow is constant. The catheter for rectal injection passes through a self-retaining rectal tip and the former can be inserted to any length desired. Asbestos ribbon is wound about the conducting tube from its junction at the bottle to the catheter. This lessens dissipation of heat and obviates the use of hot-water towels.

4. **Pulmonary Tuberculosis.**—Miller places special emphasis on the following points: The attitude of every physician toward tuberculosis should be that of constant suspicion. The history of intimate exposure to infection and a detailed inquiry into previous illnesses are of the greatest importance. A properly conducted physical examination is the cornerstone of the diagnosis, but physical signs of tuberculous toxemia are quite as important as are the signs in the lungs. Prolonged and repeated examinations are often essential. Failure to find the tubercle bacilli in the sputum and other excretions is evidence of little value. The tuberculin tests are valuable in connection with the clinical manifestations, but their exact significance is not yet absolutely determined. In general, the diagnosis is based on no one symptom, sign, or test, but on a careful correlation of all the evidence into a rational clinical picture.

5. **Tubercle Bacilli in Urine.**—Beardsley found that acid-fast and alcohol-fast bacilli are frequently present in the urine of tuberculous patients. He says that such bacilli have been proved in many instances to be capable of producing tuberculosis in animals, and, until it is conclusively proved that these bacilli are not virulent it is wise to consider all of them virulent. It is reasonable to believe that in tuberculosis tubercle bacilli are present, at times, in the blood of the individual. Tubercle bacilli may be present in the urine without a macroscopic lesion of the genitourinary organs. Although inoculation experiments are absolutely necessary to conclusively prove that a germ found in the urine is the specific bacillus of tuberculosis, nevertheless a bacillus that retains the carbol-fuchsin stain after thorough decolorization with Pappenheim's solution is likely to be the tubercle bacillus. Beardsley emphasizes that disinfection of the urine and feces of tuberculous patients is required to free them from danger of transmission of the disease to others.

8. **Error in Diagnosis.**—Koenig cites a case in which a serious affection of the throat and of the whole organism was not recognized on account of the resemblance, or rather non-resemblance, which exists microscopically between the *Spirochæta pallida* of Schaudinn and the spirillum of Vincent.

18 Skin Disinfection with Iodin in Abdominal and Other Operations. C. Jewett, Brooklyn.

15. **Medical Education in France and Germany.**—St. Jacques says that in Germany laboratories are numerous and better equipped, and research work is extensively carried on. Clinical facilities are greater in France. Paris excels in skin, nervous and genitourinary diseases, in surgery and bacteriology. Postgraduate work is more practically organized in Germany.

17. **Hygiene of Air Passages.**—Judson draws attention to the fact that coughing, sneezing and blowing the nose do not relieve the subject, but that by increasing the congestion and irritation of the air passages they increase the condition which the patient seeks to relieve. By proper control of these things suffering will be lessened.

23 Thrombosis of the Left Femoral Artery. C. S. Walker, Keene, N. H.

19. **Cancer Immunity.**—Gay claims that it is justifiable to regard the pre-metastatic period of a tumor as a period during which the animal shows reaction products to cancer tissue, and during which period the animal is able successfully to combat a generalized infection of the cancer. In those cases in which spontaneous resorption of the tumors occurs, which are relatively frequent in animals and have also been described in human beings, it may be supposed that the resistance of the individual has succeeded in overcoming the cancer. From experiments carried out by Gay in animals, it would seem possible that during this pre-metastatic reaction

period, the resistance of the individual may be increased by re-inoculation of the tumor, or possibly of products of the tumor, to such an extent that the resorption of the original tumor may be brought about.

21. Postoperative Dilatation of Stomach.—Torbert points out that acute postoperative dilatation of the stomach is not so rare as the literature would lead one to believe. The diagnosis can usually be made by having the subject in mind, especially when we have the presence of distention, vomiting of large amounts of brownish-green fluid, no necessary rise in temperature, rapid pulse and a rapidly increasing collapse. The passage of the stomach tube will usually establish the diagnosis. According to reported cases, the condition is very fatal, Laffer stating that 63.5 per cent. of those affected die. When the condition is recognized early, however, most of the patients respond well to treatment, the high mortality figures being probably due either to a late diagnosis or to a complete failure in recognizing the condition. The importance of the stomach tube as a part of an operation outfit is emphasized by the existence of this comparatively recently recognized condition.

22. Esophageal Malformations.—Robertson cites a case in which the esophagus consisted of two distinct portions entirely separated from one another. The upper portion opened normally above into the pharynx, but below it ended in a blind cul-de-sac, the lowest portion of which was 1.4 c.c. above the tracheal bifurcation. The lumen was about uniform throughout; the thickness of the wall increased slightly toward the lower end. The mucous membrane was pale, smooth and slightly thrown into folds. The lower moiety was in all respects smaller than the upper part. Below it opened normally into the stomach, but above it formed a fistulous communication with the posterior wall of the trachea at a point 8.4 mm. above the bifurcation and 6 mm. below the pouch-like end of the upper part. The mucous membrane was smooth and pale. The pylorus was freely patent, measuring 15 mm. in circumference. The mucous membrane of the stomach and intestines was smooth and pale.

26. New Method for Inducing Local Anesthesia.—Ransohoff publishes a case preliminary to a series of experiments on a new method of local anesthesia—that is, by injecting a mild cocain solution directly into the artery supplying the part to be anesthetized. The patient had been suffering for three years from a chronic osteomyelitis of the hand, which became so painful as to necessitate amputation. His age and condition contraindicated general anesthesia. An Esmarch bandage was applied about the arm two inches below the insertion of the deltoid. Under infiltration anesthesia the brachial artery was exposed and the needle of a hypodermic syringe inserted into its lumen, and 1 c.c. of a 2 per cent. cocain solution injected into the artery in the direction of the blood current. After a lapse of two minutes the anesthesia was absolute, and an antebrachial amputation was done entirely without the knowledge of the patient.

42. Cultivation of Bacillus Lepræ.—The experiments conducted by Clegg on the cultivation of the leprosy bacillus were confined entirely to an attempt to grow the organism in symbiosis. Believing that the leprosy bacillus derives its nutrition from the products of the tissue cells in the lesions in which it is encountered, and from the fact that it occurs so frequently within the protoplasm of these cells, an organism was selected which could be cultivated and which corresponded in a degree to the living tissue cells; that is, an organism containing a nucleus and protoplasm, the ameba. The culture medium was composed of agar 20 grams, sodium chlorid 0.3, extract of beef 0.3; it was otherwise prepared in the same manner as ordinary agar media for bacteria, the finished product giving a reaction of 1 per cent. of alkaline to phenolphthalein. The medium was then placed in tubes and sterilized.

The culture medium, when it is to be used, is melted and poured into sterile Petri dishes and allowed to harden before being inoculated. The material containing the ameba is then spread in a thin layer over the surface of the medium. If the proper symbiotic bacteria are present, the ameba will develop in from two to ten days, depending on the source of the ameba and the number and character of the bacteria present. A culture of ameba was obtained from a dysentery stool and after a sufficient growth of the ameba had occurred to overbalance the original symbiotic bacteria growing with the ameba, that is to say, when it would have been necessary to add a fresh supply of the symbiotic bacteria to the culture in order to obtain a further development of the ameba, leprosy bacilli were added instead.

The inoculation of the plates with leprosy bacilli was accomplished by smearing the surface of the medium containing the ameba with a portion of the pulp of a leper's spleen, and incubated for six days at a temperature of 37 C. Microscopic preparations were then made from the cultures and stained with hot carbol-fuchsin solution, decolorized and counterstained by Gabett's method. A great number of leprosy bacilli were found to be present, together with short, plump. acid-fast bacilli, occurring mostly among the clumps of the leprosy bacili, and associated closely with the ameba. Those organisms which from their morphology were evidently leprosy bacilli were undoubtedly carried over from the original source, that is, from the spleen. Transplants from these plates were immediately made on fresh plates containing ameba and their symbiotic organisms, and incubated for two days at the same temperature. Slides were then prepared from this series of cultures and stained in the same manner. Microscopic examination showed that the short, plump acid-fast bacilli had increased in number, showing conclusively that the organism was multiplying. Control plates made at the same time with the same ameba and in the same manner, except without the material from the leper's spleen, showed no acid-fast organisms. In the cultures from two cases an acid-fast bacillus is growing and multiplying, which although it differs from the leprosy bacillus in morphology, nevertheless may be that organism, as we know nothing regarding the morphology of *Bacillus lepræ* on artificial media.

44. **Treatment of Cholera.**—Rogers found that the severity of the cholera attack is in proportion to the loss of fluid and salts from the blood, which, in all but mild cases of the disease, it is desirable to replace. This can best be done by the intravenous injection of about four pints of hypertonic salt solution, two drams of sodium chlorid to the pint (1.35 per cent.) being a suitable strength. The use of this solution has reduced the mortality during 1908 in the Calcutta Medical College Hospital by nearly one-half. The salt solution may be given intraperitoneally with great advantage. Postcholeraic uremia is associated with deficient blood pressure, and should be treated by methods which raise the tension in the arterial system.

63. **Dental Disease.**—Upson puts on record a few observations made during the past two years in a broad and important field, that relating to dental diseases in connection with nerve strain and with the psychoses, melancholia, mania and dementia præcox. He says that of all cases of neurasthenia and the psychoses not due to obvious physical causes, such as digestive disorders and eyestrain, the great majority, possibly four-fifths in men and three-fifths in women, are due to dental disease. In several of his patients, severe nervousness, insomnia and melancholia have begun soon after extensive bridgework and capping. These symptoms have persisted several years without pain, and relief has followed only after removal of irritation in the teeth and jaws. Upson reports a number of cases in support of his contention.

72. **Family Psychoses.**—Fitzgerald believes that there is an evident tendency when several members of the same family of one generation become insane, to show a fairly uniform reaction type, so that it is possible to classify these cases as belonging to one given clinical group. There is also evidence to show that with succeeding generations, a psychosis occurring in each generation, there is a lowering of the reaction type and a likelihood of deteriorating psychoses developing, and still further from the original antecedent a probability of gross defectives appearing.

77. **Diarrhea of Gastrogenous Origin.**—The diarrheas of purely gastrogenous origin can not be said to be of very frequent occurrence, but, though relatively infrequent, the stomach, according to Simon, does play a part, and he emphasizes the importance of this class of diarrheas.

80. **Acute Spasmodic Asthma Evidence of Autointoxication.**—In 1905, Eustis first called attention to the clinical significance of indicanuria, and since then he has made it a practice to include this in the routine examination of patients. The fact that he has found evidence of autointoxication in every case of asthma examined by him for four years, leads him to believe that during the attack there is some toxin in the blood, which acts similarly to muscarin, or which depresses the respiratory center to such an extent that the reflex stimulation of an inflamed nasal mucosa results in a stimulation of the constrictor fibers of the vagus. Nearly every one of these cases was relieved by diminished nitrogenous diet and measures to reduce the toxemia. Eustis employs eliminative treatment and more hygienic procedures, using few sedatives.

87. **Syphilitic and Metasyphilitic Conditions.**—Noguchi emphasizes the fact that any method in which five different factors—amboceptor, complement, corpuscles, antigen and patient's serum—are not separable, titrable and adjustable, is defective in principle and should not be recommended for diagnostic purposes. As regards the value of the butyric-acid reaction in the diagnosis of nervous diseases, the results obtained by Noguchi, together with Moore, Rosanoff and Wiseman, show that it is positive in nearly 90 per cent. of cases of paresis and tabes, and that it is nearly as reliable a diag-

nostic indicator as is pleocytosis. Compared with the percentage of positive results by the Wassermann reaction, the butyric acid test yields better results, especially in cases of cerebrospinal lues in which the Wassermann reaction is usually inconsistent.

88. **Pulmonary Tuberculosis.**—Lange believes that the thorax is peculiarly adapted for Roentgenologic examinations, but all conclusions must be based on technically perfect plates made during a respiratory "still-stand." The interpretation of the shadows must be correlated to the history and clinical findings. The Roentgen ray will register actual and definite increase in density of the lung tissues. Since the term incipient tuberculosis is a clinical (not a pathologic) one, and since the recognition of incipient tuberculosis must depend on the size, distribution and location of the lesions and on the skill of the examiner, a comparison between the usual physical examination and the Roentgen ray examination is difficult to make. For deep-lying lesions and bronchial gland involvement the Roentgen ray is superior. Roentgen ray findings point to the bronchial glands and lung hilus as the most common starting points of tuberculosis.

89. **Differentiation of Reflex Dyspepsia.**—According to Fulton, the symptoms of all primary organic diseases of the stomach are dependent on the quality or quantity of food eaten. Functional and nervous dyspepsias are independent of the diet and are dependent on the nervous conditions of the patient. Reflex dyspepsias are but slightly influenced by diet and are dependent on aggravation of the primary disease, and are absent when the primary disease is latent.

94. **Diagnostic Signs in New Kidney Growth.**—In the case of a patient who presents himself with a history of intermittent hematuria in whom no blood is found in the urine, either by macroscopic or microscopic examination, Cabot advises massaging the kidneys, one at a time, as was done in a case cited. A man, aged 47, gave a history of occasional attacks of hematuria with periods between of several weeks when his urine was free from blood. *X*-ray examination was negative. Bimanual examination of the kidneys seemed to show some enlargement of the right kidney, but not perfectly clear. The patient had been told by a distinguished surgeon that probably both kidneys were diseased and operation was not advisable. Cystoscopy revealed a perfectly normal bladder and normal ureteral openings. A catheter in each ureter for a distance of six inches drew off clear urine. On massaging each kidney separately immediately abundant bright red blood gushed out of the right ureteral catheter; none from the left. The diagnosis of hypernephroma of the right kidney was confirmed by operation.

103. **Soy Bean in Infant Feeding.**—The soy bean (*glycine hispida*), sometimes incorrectly called the soja bean, is an annual leguminous plant which originally grew in a wild state from Cochin, China, to the south of Japan and to Java. It is now being grown in various sections of this country and can be obtained in the open market like any other legumin. As regards the use of the beans in infant feeding, it seemed to Ruhräh that soy bean gruel or milk, either alone or mixed with cow's milk, might be of value in feeding several classes of cases, viz., of marasmus and malnutrition, as a substitute for milk in diarrhea, and in intestinal and stomach disorders, and in diabetes mellitus. So far, the gruel has been prepared by soaking the beans over night, stirring to remove the envelop surrounding the bean. Three times the amount of water is added to the beans and they are boiled until a smooth gruel results. This is strained, if necessary. This has the odor and taste of malt, but with the addition of a little salt is well taken, especially after the first bottle or two. The gruel is retained unusually well and seems to be digested easily. The stools are not more frequent than with other foods; they are light brown in color, like those from malted milk. This soy bean gruel has nearly the same food value as milk, and for certain children may need further dilution. About the same size feedings should be used as if milk were being given; 5 per cent. sugar may be added to increase the fuel value. Ruhräh has not used the beans in a sufficiently large number of cases, nor over sufficient periods of time to justify any further statements at this time, but he feels that properly used they will be a most valuable addition to the dietary of the sick infant. Grinding them to a bean meal would simplify matters very much, and, if success attends their use, a soy bean meal could easily be prepared.

108. **Two Interesting Dermatologic Cases.**—The reason for the report of these two cases is found in the character of the lesions, their association and mode of onset. In both there is a certain similarity as to the personal history, and the character and distribution of the lesions were identical as to region. They appeared on the tips and on the extensor surfaces of the phalanges of the upper extremities as distinct vesicles of large size, without an inflammatory areola, caused a separation of the epidermis from the corium, were filled with a sterile serous fluid, and were accompanied locally by itching, burning and heat. The first patient, a girl of 10 years, had fallen while at play, striking her hands rather severely. She complained at the time that her hands "stung," but no lesions of any type were observed, though the hands were somewhat reddened.. For relief the child put her hands under cold water and immediately lesions of the type described above appeared. She had pertussis when 2 years old, which merged into an attack of measles, apparently uncomplicated. At a later date, she had an attack of varicella, and at her sixth year, and later, suffered considerably from rheumatism in the upper and lower extremities. She had three attacks ot infectious blepharitis, complicated in every instance by a facial tic, which involved, for the most part, the muscles of the eyelids. She had had frequent mild attacks of urticaria and one severe attack which was associated with aching of the extremities. A careful physical examination showed that she was totally negative, except for enlarged tonsils, which were removed. The lesions healed without infection and there have been no recurrences.

The patient, a boy aged 7 years, while riding on the street car, suddenly felt a sense of burning pain in his hand and found what he called blisters on the ends of his fingers. The boy complained of burning and pain, with itching, and there was some local heat. He had pertussis at his sixth year, and has been subject to slight digestive disturbances for a long time past, especially in the last six months. Ever since his third year he has had a well-developed urticaria during the strawberry season, and during the last year had a severe attack of urticaria following excessive sweating while at play. He has complained of rheumatic pains in the extremities during the past winter more than during any previous winter.

121. Published in *Surgery, Gynecology and Obstetrics*, July, 1909.

122. **Aneurisms in Young People.**—McGraw reports two cases of aneurism in young men 16 and 17 years of age. Both aneurisms were associated with great dilatation of the heart and, in both patients, the arteries were soft and fragile. There was no history of rheumatism or other acute infectious diseases.

123, 135, 137, 139, 140.—Abstracted in THE JOURNAL, July 31, 1909, pp. 407-409.

125, 127, 129, 131.—Abstracted in THE JOURNAL, July 24, 1909, p. 319.

126. **Histopathology of Goiter.**—Shepherd and Duval studied fifty-nine cases. Eighteen were unquestionably cases of Graves' disease, two of which proved fatal. The infolding and budding of the acinal epithelium was present in some parts of the gland in 20 cases. The gland presented tumor formation in three cases of the series, viz., carcinoma in one, intercystic papilloma in another, and angioma in still another. Chronic inflammation in the form of lymphoid cell and plasma cell infiltration, together with an increase in fibrous tissue stroma, occurred 29 times. Eleven cases were of a simple cystic nature.

128. **Operative Treatment of Heart Wounds.**—Peck reports a case of wound of the right auricle which was sutured, with recovery of the patient. He also tabulates 158 cases of sutured heart wounds.

130. **Surgery of Lung Tuberculosis.**—Freeman says that the healing of stubborn tuberculous pulmonary lesions is favored by collapse of the lung. This may be obtained by (a) artificial pneumothorax; (b) extensive extrapleural resections of all the ribs, with removal of their periosteum; (c) local resections of ribs, especially at the apex. The first method is not always applicable, owing to adhesions and to induration of lung tissue, while the second is difficult and dangerous, and should be employed under exceptional conditions only. The third method is applicable to obstinate troubles at the apex, and can be employed alone or in conjunction with an artificial pneumothorax, according to circumstances. Its full benefit can not be obtained, however, unless the removal of the ribs, which need not include their periosteum, is followed by the application of firm external pressure in the manner suggested by Freeman.

138. **Vesicointestinal Fistulæ.**—Parham and Hume summarize their article as follows:

1. Establish clearly the nature of the lesion.
2. *Determine the location of the opening in the bladder and in the intestine, when possible; this can usually be done by the modern methods of exploration of the rectum and bladder, and by a study of the intestinal contents passed per urethram.*
3. Medical treatment is always to be tried for a reasonable time, as some patients have recovered under such management, and certain fistulæ of syphilitic origin have been absolutely cured by appropriate treatment.
4. The prognosis in patients untreated is generally bad and spontaneous cures are rare.
5. Ascending infection of the kidneys is one of the most important *sequelæ, and this is always to be feared in patients who do not* recover within a reasonable time.
6. Colostomy relieves the symptoms though it does not cure the condition, but it is to be tried in all cases in which a radical procedure is not possible.
7. Radical operation is always to be preferred, when practicable; from below, when the fistula is situated within 4½ inches of the sphincter in suitable cases; intraperitoneally, for high-placed fistulas the viscera being separated and direct suture of each opening done.
8. When the radical operation can not be done, bilateral or total exclusion of the portion of the intestine involved, may be done when there is no urinary flow into the bowel; this not being advisable, one of the shunting anastomosis procedures should be done, or simple drainage of an intermediary pouch resorted to.
9. The suprapubic intravesical suture of the bladder orifice is not to be recommended, because difficult of execution and uncertain in result.
10. Exploratory laparotomy is indicated in all cases in doubt to determine the location of the fistula and the operation of choice. Colostomy is to be regarded as an operation of last resort and applicable only in those cases in which the artificial anus may with certainty be placed above the fistulous communication with the bladdder.

143. **Massive Keloid of Face and Hands.**—In Porter's case the patient's face presented masses of keloid extending from the hair line on the forehead over the whole face, including both ears. A small portion of the right cheek was visible, the eyes appearing as slits in the midst of the exuberant overgrowths. Slight impairment of hearing; vision in left eye was interfered with; mouth could be opened only half an inch. There was excessive keloidal growth on the backs of both hands and the lower third of forearms, the fingers being hyperextended, twisted and distorted. In numerous places the keloidal tissue was eroded, with some foul discharge from the sulci between adjacent lobules.

After many operations, there has been a gradual but distinct abatement of the tendency to form keloidal tissue. The forehead is covered by shiny, movable skin, resulting partly from natural healing and partly from skin grafts. There is some keloid about the deformed ears, but both show evidence of their presence. The nose and cheeks are fairly normal, but there is still some ectropion in spite of the numerous operations. The hands have been improved so far as ability to grasp objects with the thumb is concerned, but dorsal hyperextension of the fingers still persists. Roentgen ray exposures seem to have been of no value.

1 *The Belfast Medical School. Sir W. Whitla.
2 *Progressive Medicine and the Outlook on Tuberculosis. R. W. Philip.
3 *Progress in Intestinal Surgery. A. E. Barker.

1. **The State of Medical Education.**—This address consists, in the main, of a historical sketch of the Belfast medical school, touching briefly on the present state of medical education, especially condemning the congestion of the curriculum. Whitla believes in the sending out of men qualified immediately to enter on the routine practice of their profession. We are, in some respects at least, behind the results obtainable in the old days of apprenticeship. He says that the preliminary and intermediate periods, amounting to three years out of the minimum of five years, must be shortened, and the clinical period of study must be increased if we are to train more efficiently, and turn men out of our teaching institutions properly equipped for their serious life work. How is this readjustment of the curriculum to be accomplished? Obviously, an enormous aid to it would be a compulsory examination in experimental physics and chemistry at matriculation. Such an examination could never dispense with the necessity of a complete academic course in these subjects; it would ensure the student having some knowledge of the principles of both sciences from the start of his college work, and enable the average young man easily to pass his further examinations in them within a period of twelve months from matriculation. Already the old notion that the stage of school life should be entirely devoted to purely literary studies is showing signs of yielding to the urgent pressure of modern ideals, which demand that boys must be trained to observe and reason on the operations of the natural forces continually manifesting their presence in the world around them. Owing, however, to the present unsatisfactory arrangements for the teaching of science in the majority of the secondary schools, little relief is immediately to be expected from this method of shortening the curriculum of the preliminary subjects, though we can confidently count on a steady improvement in the amount of elementary scientific knowledge possessed by medical candidates presenting themselves for matriculation. There is a growing conviction, amounting among those best qualified to judge aright in this matter to a consensus of opinion, that a prolongation of the period devoted to clinical studies can be achieved (without unduly lengthening the entire curriculum) only by a radical change in the method of teaching the entire group of preliminary and scientific subjects. The teaching of these subjects must be conducted with due regard to their bearing on the special requirements of the student of medicine.

2. **Progressive Medicine.**—Philip discusses fully the development of knowledge of tuberculosis, believing that it would be well to limit attention to one department, which illustrates in striking fashion the extraordinary revolution of thought which has occurred in little more than a generation.

3. **Intestinal Surgery.**—Barker gives a short review of the gradual evolution of intestinal surgery from the point of view of one who, though still in his fifties, has seen it in his own time. He says that this evolution has not been the result alone of the better conception of asepsis, much as we owe to it. Nor has it been due altogether to improved manipulative skill. *It has resulted from clearer views on the vital processes concerned in all lesions within the abdomen.* These we have gained partly from closer clinical observation, aided by what we have learned from the anatomist, the pathologist, bacteriologist, biologist and physicist, and from careful sifting of our experiences, whether of failure or success.

7. **Chronic Rheumatic Myositis.**—Yawger believes that the most frequent cause of the so-called gouty or rheumatic pain is a form of chronic myositis. Among the causes affecting this condition is heredity, there being a distinct family tendency to these diseased muscles. The effects of climate and weather are most marked. Chilly and rainy weather often causes the indurations to become painful; it is sufficient to be within the outer limits of storm conditions and not necessarily within the area of rainfall. They may appear at almost any time of life. While probably no voluntary muscle enjoys an immunity there are sites of predilection, the most common of which is in the muscles of the head and neck. This he believes is due to the exposure through lack of covering to which this part of the body is necessarily subjected. The gluteal, lumbar and deltoid regions, and calf muscles are often involved. The muscles may be invaded at their points of insertion, as in those attached to the superior curved line of the occipital bone and those inserted into the processes of the upper cervical vertebræ; or the infiltrations may appear within the bodies of the muscles as is frequently seen in the abdominal wall, and in the sternomastoid muscles near the level of the thyroid cartilage. At times the infiltration extends to the periosteum to which the muscles are attached and also to the fascia. The pathology of these diseased muscles is largely hypothetic for the reason that people do not die from this condition. The muscle infiltration may be due to the deposition of an excess of the salts of uric acid or an allied substance, with the later formation of connective tissue. Yawger has known vigorous massage treatment of a patient with extensive indurations to be followed by an attack of acute muscular rheumatism. It seems probable that this formation of indurations is a manifestation of a metabolic disturbance autotoxic in character. At all events, it appears that as soon as good circulation is established relief is at once experienced. Whatever this muscle poison is, many of its subjects have had bilious attacks in childhood, and in advanced life they often suffer from arteriosclerosis. The mistakes in diagnosis to which these rheumatic deposits give rise are very numerous. Many cases of cephalalgia are of this variety; involvement of the intercostal muscles has been taken for intercostal neuralgia and pleurisy; in the abdominal wall for acute and chronic appendicitis, gastric ulcer, abdominal and pelvic adhesions, calculus of the kidney; and floating kidney; involvement of the gluteal region for sciatica and hip-joint disease; in the neck they have been mistaken

for swollen glands. The treatment consists of a thorough course in massage.

23 *Cirrhosis of Liver with Ascites—Omentopexy—Recovery. E. R. White.
24 Double Coxa Vara and Tuberculous Meningoencephalitis—Recovery. E. R. White.

23. **Omentopexy.**—A girl of 9 years had had an abdominal swelling since birth, and had always worn an abdominal binder. Eighteen months ago the swelling gradually increased. She tired easily with shortness of breath on exertion. The liver was enlarged upward and downward half-way to the umbilicus, and the edge was well-defined and distinctly nodular. The spleen was also enlarged, extending four fingers' breadth below the costal margin, and there were also definite signs of ascites. Two months after admission, under chloroform, the abdomen was opened in the midline by a five-inch incision. The cavity was dried, and the liver exposed, which was of a typical hobnail type. The peritoneum over liver and spleen, and the parietal peritoneum over a corresponding area, were rubbed with gauze. The great omentum was located, and the greater portion, six inches by six inches, was stitched by catgut to the anterior parietal peritoneum. The abdominal wall was then completely closed, layer by layer. A small incision was made more laterally over the right lobe of the liver, which was exposed and then sewn to the abdominal wall by four strong catgut sutures, and the wall again closed. There was no immediate change, as the abdomen filled with fluid, and was tapped as usual three times in five weeks. In three or four weeks after operation an improvement was noticeable. The urine passed daily increased from ten ounces to twenty to thirty ounces. The abdominal measurement became less and the general condition of the child was better. Two months after the operation the child was bright and happy, and running about. There are no signs of ascites. The liver is shrinking in size.

28 Adenoids and Nocturnal Enuresis. L. Williams.
29 *Pulmonary Tuberculosis in Young Children. J. Miller.
30 *Congenital Hernia. J. B. Barrett.

29. **Pulmonary Tuberculosis in Young Children.**—Miller suggests the following as the simplest method of classification, and one which includes all types of the disease: 1. Disseminated metastatic tuberculosis (miliary tuberculosis). 2. Caseous bronchopneumonia, or merely caseous pneumonia. 3. Fibrocaseous pneumonia. Both of the last two conditions may be complicated by the presence of cavities.

30. **Congenital Hernia.**—In Barrett's case the hernia was a large one and never disappeared into the abdomen. It could not be reduced entirely by taxis. Attempts at reduction seemed to pain the child. Moreover, the nurse in charge said that the child would sometimes cry as if in pain. An incision was made in the usual line for inguinal hernia in children. The sac was opened and an attempt made to return the contents to the abdominal cavity. This proved difficult, and it was then discovered that the appendix was adherent to the left testicle, an unusual condition, which explained the symptoms before operation. The free end of the appendix was also adherent to the cecum, which was also in the sac. The adhesions were ligatured and cut. The appendix was removed, as it was thought that the adhesions were probably due to inflammation in it, and the contents of the sac returned to the abdomen. The internal ring was extremely large, and three sutures were employed to close the conjoined tendon to Poupart's ligament.

32. **Polypoid Endometritis.**—Nyulasy believes that not only is polypoid endometritis not a malady of great rarity, but, on the contrary, is one of much frequency, attended by serious and sometimes fatal consequences, and liable to be met with in any woman during the child-bearing epoch. It accounts for much of the otherwise inexplicable mortality still occurring among puerperal women as the result of sepsis, more especially in private practice, in spite of the improved modern methods in the conduct of delivery now generally adopted. Polypoid decidual endometritis is the most important disease of the decidua, and is a frequent cause of abortion. It is a result of pre-existing chronic endometritis beginning prior to, or coincidentally with, pregnancy, and continued into the puerperium, during which acute processes are grafted on the chronic condition in consequence of septic infection. The most conclusive evidence, however, that polypoid endometritis usually commences prior to, or during pregnancy, is furnished by the fact that in many cases it is found to be distinctly syphilitic in origin, as evidenced by the history and microscopic appearances of cases examined. An interesting point is that in many instances the mothers show no external signs of constitutional syphilis, thus illustrating Colles' law; but that the mother does not become actually immune and escape serious lesions in these cases is shown by the very existence of syphilitic endometritis. During the past ten years Nyulasy met with over 100 cases in private and hospital practice, and, at the very lowest estimate, he says that it will be encountered in from 3 to 5 per cent. of all pregnancies, whether ending prematurely or at full time. Many cases of adherent placenta are due to it. In the majority of cases it is really a condition superimposed on and secondary to polypoid endometritis, for which it is usually mistaken. But from a pathologic, surgical and medicolegal standpoint, the existence of polypoid endometritis in the puerperium is of infinitely greater importance than the fact that there may be fragments of placenta adhering to the polypoid masses, because it is essential to remove these masses in order to save the life of the patient. Early curettage, by means of the ungloved finger or fingers, and a large-looped moderately sharp curette is essential for the satisfactory removal of polypoid conditions of the endometrium in the puerperal woman. By the early resort to this method such a formidable operation as hysterectomy in such cases would never be needed.

34. **Ligature of Ovarian Vessels.**—The operation advocated by Gray is performed in the following manner: The abdomen is opened by a vertical suprapubic incison, from ½ to ¾ inches to one or other side of the midline. Both layers of the sheath of the rectus and the peritoneum are opened in a corresponding line, the rectus muscle being displaced outward. Having decided that ligature of the ovarian vessels is feasible, the ovary of one side is pulled forward and away from the side of the pelvis. This makes the vessels taut and brings into evidence the "clear space" in the outer part of the broad

ligament through which fine silk ligatures (No. 1) are pulled by a handled needle or ligature carrier. If the ovaries are prolapsed into Douglas' pouch the ligatures are placed at such an interval that, when the vessels are firmly tied, the part between the ligatures resected, and the ends of the threads tied together so as to approximate the "stumps" the ovaries will lie on the brim or just immediately below the brim of the pelvis. (This procedure is similar to the usual operation for varicocele in the male). Gray prefers to arrange the ligatures, especially if the veins are varicose and tortuous, so that the ovaries are slung well up, because, owing to stretching of the vessels afterward, they tend to settle in their normal position. When the ovaries are not displaced the vessels are merely divided between two ligatures, the ends of which are tied together. If the "raw" ends of the vessels protrude, the peritoneum may be stitched over them with fine silk or catgut, so as to prevent the formation of adhesions. In cases in which there is much tension or a likelihood of postanesthetic vomiting, it is well, before tying, in order to prevent slipping, to pass one end of each ligature transversely through the leash of vessels above and below the site of ligature, respectively. In some cases adhesions under the lower part of the sigmoid flexure have to be separated in order to allow the necessary amount of vessels to be removed.

43 *Roentgen-Ray Treatment of Ringworm of the Scalp. (Radiothérapie des teignes; des critiques qu'on lui a faites; des accidents qu'elle peut causer et des moyens de les prévenir.) R. Sabouraud.

43. **X-Ray Treatment of Ringworm of the Scalp.**—Sabouraud has been the pioneer in this line of treatment and has had five years of experience and favorable results with an annual average of 500 children thus treated. He here discusses the possible objections to the method, the danger of injury of the brain and of rendering the part exposed permanently bald. He has never witnessed anything which even remotely suggested injury of the brain in any instance, although he has kept careful watch for evidences of such. At first he did not venture to apply this treatment until the children were over 2 years old and the fontanelles closed, but later he found that this made no difference and he now applies the *x*-rays at any age. He has never observed any nervous symptoms or agitation or depression, no modification in the pulse and not even a headache in his 2,000 scalp ringworm patients thus treated. At the same time, it is easy to induce a dermatitis which may kill the hair in the part, and he warns that extreme care is necessary to avoid overexposure and that no one should apply this method of treatment unless he has well studied the technic for this special affection. A trifle of excess does no harm in Roentgen treatment of an epithelioma, but it may produce a permanent bald spot on the scalp. He measures the strength and duration of the exposures with a special pastille made with platino-cyanid of barium mixed with amyl acetate collodion. As sunlight affects it, the exposures are always made in semidarkness, and he warns that when the radiometer is taken to the light to examine it, this is liable to affect its tint misleadingly; it must also be borne in mind that while the radiometer is being examined the *x*-rays are still continuing their work on the scalp, and they thus get in more work than is indicated by the index. He gives a number of suggestions for guarding against overexposure of any one part, warning especially that restless children are liable to dislodge the protecting shields over parts that have already been sufficiently exposed, and thus give them an extra dose. If the head of the child is so small that it rounds up into the "localizing tube," this is liable to increase the dose received. Another point to be borne in mind is that previous medicinal applications to the scalp render it more sensitive to inflammation. In several cases, a localizing x marked on the skin with iodin caused a delay of three weeks in the growing of the hair over this x. The swinging of the apparatus out of the center is also liable to cause a misleading exposure as the radiometer then does not get the full force of the rays.

45. **The Transthoracic Wave as Sign of Cyst in Liver.**—This sign was mentioned in the Paris Letter, July 24, page 308.

47. **Graft of Rabbit Eye After Enucleation of Human Eye.**—Lagrange reports that in 25 cases he has implanted a rabbit eye after enucleation of the eye of a patient, and has been able to follow the outcome to date in 13. The results have been extremely satisfactory, the eye healing aseptically in place and not shriveling more than one-half on the average, never more than two-thirds, the graft answering its purpose admirably in every instance. The engrafted eye shriveled less in the younger patients. He describes his preliminary experimental research and the technic for the operation. In 3 patients, aged 6, 20 and 28, the engrafted eye provided an elastic, living, large and permanent stump, thus rendering the conditions ideal for the artificial eye later.

49. **Pneumonic Plague.**—The epidemic described by de Brun comprised only four cases after the true nature of the atypical pneumonia in question was recognized, but all proved rapidly fatal, as also the few cases retrospectively diagnosed. The difficulty of diagnosing this form of plague when it first appears in a locality is the greatest obstacle in prophylaxis. Certain features of the disease suggest that the pneumonic form of plague is a special septicemic variety with coexisting variable pulmonary or bronchial lesions. This conception of pneumonic plague as a septicemia aids materially in its early differentiation, as also the absence of an initial chill, and sometimes of sharp local pain, or the pain may be experienced in some unusual location, near the apex, in the spine or axilla. The dyspnea is extreme and is accompanied by an indescribable sense of oppression in the chest, and the cough may be incessant, smothered, as if whispered, or there may be no cough at all. The expectoration may be profuse or scanty, and may suggest the sputum of bronchitis, or it may be blood-tinged and foamy, but it never resembles the rusty, tenacious sputum of pneumonia. The intense malaise and headache, pain in the chest, cough, vomiting and extreme prostration may suggest exanthematous typhus, but pneumonia is generally first thought of; the absence of the characteristic auscultation findings is ascribed to an atypical location and the physician waits for the next day to clear up the diagnosis. Then the general symptoms are more pronounced while the local symptoms are no more distinct, and the third day the patient succumbs. On the other hand, once convinced that the pneumonic form of plague is, above all, a septicemia, greater attention is paid to the general symptoms and they supply presumptive evidence in favor of plague; the stethoscope confirms this assumption even before bacteriologic diagnosis.

55. **Conservative Treatment of Sarcoma of the Long Bones.**—This article summarizes fourteen cases of sarcoma of the long bones treated by removal of the growth alone and thirty-three cases with resection. The results show that extensive resection of the bones, respecting the nerve and muscle apparatus, is effectual on the arm, but this technic is applicable to the leg only when the weight-bearing strength of the limb will not be impaired. A sarcoma of the femur can be resected without shortening the limb or material impairment of its strength and the same can be done for the fibula. Amputation should be reserved for the severest cases.

67 Necessity for Autopsy after Industrial Accidents. M. Letulle

58. **Repeated Cesarean Section.**—Garipuy concludes from his analysis of the literature on this subject that the obstetrician should aim to perform the later Cesarean section as near to term as possible and yet before commencement of labor as with the onset of labor there is danger of rupture of the old cicatrix. There are usually scar changes and adhesions requiring modification of the classic technic, but the literature does not show that the prognosis has been aggravated by them. Four and even five successive Cesarean operations have been performed in a few cases. The question whether to remove or merely incise the uterus in a later pregnancy must be determined by the strength of the uterus wall; if it shows signs of weakness or cicatricial tissue requires resection, hysterectomy rather than Cesarean section may be advocated, for fear of rupture in a later pregnancy. Adhesions which it is impossible to separate are another argument in favor of rendering the woman sterile thereafter, preferably by resecting the tubes between two ligatures if hysterectomy is not deemed advisable.

59. **Fat in Diet in Gastric Hypersecretion.**—Martinet's experience has confirmed that of others in regard to the great benefit derived in gallstone troubles and gastric hypersecretion from the daily ingestion of from 75 to 150 c.c. of olive oil before breakfast. The only objection is the repugnance to the oil experienced by many patients, and for these he orders the needed fat in the form of fresh milk and cream, fresh butter and bone marrow. The latter is freshly cooked and spread on bread. The substitution of olive oil for butter in cooking the food is an advantage. He has also found almonds a simple and palatable means of supplying the fat; the patient is told to eat from 60 to 80 or 100 gm. of almonds according as they are fresh or old.

62. **Traumatic Neuroses.**—Brissaud passes in review the various communications on this subject at the International Industrial Accident Congress held recently at Rome. The necessity for institutional care for the victims of industrial accidents was emphasized by several speakers; special hospitals where they could receive proper treatment with due regard to rendering the subjective symptoms objective and detecting malingering were advocated. In France it is becoming more and more the custom to hasten legal proceedings, accepting a permanent but comparatively slight impairment of the earning capacity, estimated at 5, 10 or 15 per cent., and to settle damages summarily on this basis without further delay. Windscheid has declared that too large an indemnity deprives the injured of their only means of cure—the resumption of their work.

63. **Post-Traumatic Delirium Tremens.**—Forgue relates an example of death from delirium tremens after a slight fall, which, without this complication, would have been comparatively harmless. The spontaneous pain of the contusion subsided under repose by the second day but then delirium tremens developed, fatal the sixth day. He has witnessed a number of cases of this kind and discusses the question from the standpoint of accident insurance. There can be no question as to the connection between the accident and the development of the fatal complication. The verdict of a Swiss court in a similar case reduced the indemnity on account of the chronic alcoholism, stating that the life expectancy and earning capacity must be regarded as having been much below the normal. French jurisprudence does not accept this view; it disregards entirely the previous condition and seeks to determine merely whether there is a causal connection between the industrial accident and the disability or death of the injured.

64. **Duration of Incapacity in Accidents to the Eyes.**—De Lapersonne states that in 200 cases of industrial accidents to the eyes on which he had to report to the authorities, the incapacity lasted for less than a month in 25 per cent. and up to three months in 50 per cent. and he discusses the various factors affecting the final outcome. Sympathetic ophthalmia, he states, is most liable to develop after penetrating wounds of the ciliary region, with hernia or constriction of the iris, especially when complicated by the presence of a foreign body. Consequently, early diagnosis of the foreign body is of the utmost importance and also its prompt removal, especially if it is lodged in the dangerous ciliary zone. Traumatic cataract always entails more or less industrial incapacity and there is no need to wait for its extraction; he has never found that normal conditions were restored later in cases of this kind, and the settlement of the case need not be deferred in expectation of improvement later.

66. **Measurement of Parts in Cases of Industrial Accidents.**—Desfosses uses in clinical—not precision—examinations a dressmakers' tape measure, a goniometer to measure the angles of flexion and extension of the joints, and a dynamometer to register the effort in pressure and traction. In a number of illustrations he shows the way to use them and the points for measurement of parts, direction, thickness, etc., to have the records uniform for comparison and readily controlled. The results of examination of the victims of industrial accidents should be transcribed as objectively as possible, he emphasizes, as they are to be submitted to various lay parties, and the written descriptions should be accompanied by measurements and a statement as to how the measurements were taken. The comparison between the injured and the sound parts and between the same parts after certain intervals may throw light on the case and exclude malingering by objective data.

75 Lightning Treatment or [illegible] Funkenbehandlung.) F. Davidsohn.

68. **Psychotherapy.**—Oppenheim replies to Dubois' article, summarized in The Journal, August 7, page 493, endorsing his views but complaining that they do not pay sufficient at-

tention to the morbid anatomy element in anguish conditions. The disturbance is based to a greater or less extent on an abnormal excitability of the centers presiding over vasomotor functioning and the functioning of the viscera. Courage and will power may be enthroned in the brain while anguish and dread tyrannize in the cerebellum. Regard to this fact imposes caution in estimating motives, actions, properties and character manifestations, while at the same time it points the way to effectual physical measures which may restore conditions in the cerebellum to normal. The psychotherapy must be supplemented by the tried and indispensable means of influencing the excessively irritable vasomotor centers; dietetics, outdoor life, hydrotherapy, electrotherapy, gymnastic exercises, etc.

69. **The Appendicitis Collective Inquiry.**—Rotter reviews the 3,016 cases, included in the reports, from the standpoint of treatment, the conclusion being that the principle of early operation—in the first forty-eight hours—has won the victory.

71. **Roentgen Differentiation of Tuberculosis of the Lungs.**—Cohn gives the reasons for the indispensable value of *x*-ray examination in the diagnosis of affections of the lungs, to supplement other diagnostic measures. He says that it is necessary to examine the lung with three forms of exposure: (1) examination of the apices, the hilus region and the diaphragm with a medium soft tube, sagittal, from front and rear; (2) exposure of the apex with a round diaphragm showing the second and third intercostal field, in the ventrodorsal diameter; (3) exposure of the middle part of the lung with the tube at the back.

72. **The Modified Technic for Seroreaction in Syphilis.**—Meirowsky gives the findings in 318 cases tested both with the Wassermann and the Stern technics. The findings paralleled each other except that the Stern technic seems to be more sensitive while it is much simpler. He advises comparative tests with both technics, as he regards the Stern modification as an advance.

73. **Action of Injected Sugar.**—Süssenguth injected about 1 per cent. of the body weight of a 50 per cent. solution of grape sugar in his experiments on rabbits and guinea-pigs, the subcutaneous injection being repeated daily. No toxic action was apparent, and the conditions in regard to glycogen did not seem to be altered in the direction of diabetes. The findings suggest that the sugar in diabetes should not be incriminated for the symptoms to the extent some assume.

74. **Frequency of Inherited Syphilis in Berlin.**—Heller compiled this statistical article for the inauguration of the new asylum at Berlin for children with inherited syphilitic taint. The statistics are very defective, but they show a proportion of from 0.9 to 2.53 per cent. children with inherited syphilis among the younger inmates of the hospitals and asylums of Berlin. The unfavorable prognosis of inherited syphilis changes wonderfully for the better when it is recognized in time and treatment instituted at once. Welander's success in the similar institution at Stockholm encourages efforts in this line. Only two of the children inmates of his home have died since it was founded nine years ago, and an intercurrent disease was responsible for these fatalities.

81 *Indicati ncy in Diabetics. (Indikationer chwangerschaft bei zuckerkrank
82 *Hyperer Treatment of the Urethra. (Die Harnröhre mit heissen Sonden.)

76. **Treatment of Bronchiectasis.**—Hoppe-Seyler lays great stress on the prophylaxis of bronchiectasis and urges that this should be borne in mind in all cases of bronchitis, especially in the aged. Every effort should be made to ensure complete evacuation of the secretion from the air passages. In the elderly the reduced sensitiveness of the bronchi, the less elastic thorax and lungs and the weakness of the chest muscles, all cooperate in preventing ample expectoration. Such patients should make copious use of stimulant expectorants, and they should be made to change their position often, reclining at times horizontally or with the pelvis raised to promote expulsion of the secretions. When resolution drags in pneumonia, the patients should use breathing exercises and lie on the sound side to prevent consolidation and stiffening of the lung tissue which hampers evacuation of the bronchial secretions. Early evacuation of pleural effusions will aid in preventing development of adhesions. Chronic bronchitis should be healed or kept under control with turpentine and creosote derivatives. Treatment of the cylindrical form of bronchiectasis is the same as of chronic bronchitis; benefit may be derived from breathing exercises supplemented by compression of the lower part of the chest; this the patient can do himself by putting his hands on the sides of his chest, and bending far over, as if bowing low, the forcing up of the diaphragm in consequence thus exercising the lower part of the lung. In sacculated bronchiectasis of the lower lobe it is difficult to evacuate the secretion, but this can be promoted by reclining slanting, the shoulders low, or even the true Trendelenburg position. This is sometimes surprisingly effectual and the patients should train themselves to recline in this slanting position an hour or so morning and night or even longer, changing from side to side until the position is found in which most copious evacuation occurs. It can be promoted by compression of the region involved. If the patients are not too weak, out of door exercise and climbing will benefit by the greater respiratory demands. Inhalation of fumes of turpentine poured on boiling water may aid in softening and expelling the sputum. If operative measures become necessary, his experience speaks in favor of mobilization of the chest wall by extensive resection of ribs, thus allowing it to sink in and compress the lung, closing up the formerly gaping cavities. This should be followed by inhalations and breathing exercises, opening into and draining the cavities as the last resort.

81. **Pregnancy in Diabetics.**—Offergeld states that 30 per cent. of 57 diabetic women died in coma during or soon after a childbirth, and 14 others died during the fourteen months following, either from the diabetes or from complicating pulmonary tuberculosis—a total mortality of 50 per cent. in 57 cases; 51 per cent. of the children were stillborn, 11 per cent. died soon after birth, and 7 per cent. died in infancy from hydrocephalus or diabetes—a mortality of over 66 per cent. In the 25 cases in which the fetus succumbed, 17 of the women died in coma. It is thus evident that the diabetes and the pregnancy have a most unfortunate influence on each other, but it is possible to avert evil consequences in the mild and moderately severe cases in many instances by dietetic measures, bearing in mind the requirements of the growing fetus in respect to needed calories. If the diabetes becomes aggravated by the pregnancy, the tolerance reduced, the patient losing weight, and the subjective symptoms becoming aggravated, the woman should be delivered from the stress of the pregnancy; acidosis alone does not indicate this unless it is constantly accompanied by albumin and tube casts. The course in previous pregnancies is an important guide to treatment. Coma is generally preceded by certain premonitory symptoms, acidosis and increase in the ammonium salts, and consequently the latter may prove of decisive importance under certain conditions. Coma once installed, the fetus inevitably succumbs and as the coma determines the outcome there is no necessity for interrupting the pregnancy, but if labor is under way the woman should be delivered rapidly and with the least possible effort. Diabetic parturients do not seem more exposed to infection or more disposed to hemorrhage than normal women. General anesthesia should be avoided if possible, but ether should be given the preference if such becomes necessary.

82. **Hot Sounds in Hyperemic Treatment of Urethritis.**—Porosz uses a sound arranged to permit a current of hot water to flow through it without escaping into the urethra. The hyperemia thus induced softens and loosens the tissues and aids in dilatation of the stricture.

87 *Case of Gangrene of the Leg after Constriction by Momburg's Belt. (Fall von Gangrän des Beins nach Unterbindung der Arter. femoralis unter Momburgscher Blutleere.) F. Kempf.

83. **Varicocele.**—Istomin reviews the anatomy and histology of the spermatic veins and the importance of mechanical factors in the origin and the cure of varicocele. A suspensory and dietetic measures should be tried first in all cases; if they fail, an operation should be advised, and this should aim to form an "internal suspensory." Resection of the vein is justified only after other measures have failed to induce a permanent cure. The resection should not be done in the scrotum but in the inguinal ring. He warns that the wearing of a suspensory may increase a tendency to hypochondria, and that extreme hypochondria should contraindicate an operation for the time being, as such surgery on the mentally unsound may result in harm both for patient and surgeon. In conclusion he advocates a technic which he found beneficial in the two cases in which he has applied it. Through a small longitudinal incision in the tunica vaginalis at the inguinal ring he passed a thread through the spermatic cord and through the cellular tissue on the anterior surface of the pubis just below the ring, tying it there while two other sutures held the tunica vaginalis to the external and internal pillars of the inguinal ring. The central portion of the spermatic cord was readily reduced through the inguinal ring while the sutures held the testis at the desired height and they were in such firm tissues that there was no danger of their pulling out. A bibliography of 193 titles is appended.

84. **Transplantation of Entire Organs.**—In 7 animals the carotid and thyroid gland were reimplanted in the same dog and in 6 were transplanted into another dog, while in 7 an artery and kidney were reimplanted in the same animal and in 6 in another animal, with 5 operations on vessels alone. The early and ultimate findings are listed; they show that transplantation on the same animal alone promises complete restoration of function.

85. **Trigeminal Neuralgia.**—Büdinger reports the complete cure for three and a half years to date after an operation for recurrence of trigeminal neuralgia a few months after a primary peripheral and ineffectual operation. The oval foramen was opened and the neuroma-like enlargement of the central stump was released from its confined bed and the nerve resected from the base of the skull to the ganglion. The oval foramen was then plugged with bone to prevent regeneration.

86. **Treatment of Felon.**—At Bier's clinic a felon is regarded as a traumatic inflammation originating in the subcutaneous tissue from invasion of bacteria through some possibly insignificant lesion, but soon involving the periosteum. Under constriction hyperemia the process healed in an average of 23.5 days in 33 cases; under suction hyperemic treatment in 35.5 days in 20 cases, and in 40.3 days in 12 cases treated by ordinary operative measures. The induced hyperemia reduces the pain at once and permanently and the bone is protected against sequester formation or the sequester heals into place again. The functional outcome was also better under conservative than operative measures. Skiagrams of a number of the cases are given, the final conclusions being in favor of a minute incision with constriction or suction hyperemia as superior to all other methods of treatment, assisting the organism in its struggle against the infection, promoting natural healing processes and best ensuring a good functional outcome.

87. **Gangrene After Application of Momburg Belt to Arrest Hemorrhage.**—The gangrene developed a week after resection of 3 cm. of the femoral artery on account of injury from a pitchfork, a handbreadth below Poupart's ligament. The patient was a young man and he had lost much blood before the operation. It might have been better, Kempf remarks, if collateral circulation had been promoted by saline infusion before attempting the operation or afterward, but this was not deemed necessary at the time. The operation was completed in twenty minutes, but as the tourniquet first applied interfered with the operation, the rubber tube was wound around the waist according to Momburg's technic. It gave no better results, however, than an ordinary tourniquet from the standpoint of development of gangrene.

88. **Diagnosis of Tuberculous Eye Affections.**—Löhlein declares that the new local tuberculin tests show that tuberculosis is a much more frequent and important factor in eye affections than has been previously recognized. He disapproves completely of the ocular tuberculin test as liable to do damage. The preferable technic seems to be to apply first the cutaneous test; a negative reaction seems to exclude tuberculosis. The subcutaneous technic is the most valuable and reliable. The cutaneous test first, followed by the subcutaneous allows surprising insight into the nature of ocular lesions.

91. **Treatment of Peritonitis.**—Bertelsmann discusses mainly the diffuse peritonitis following appendicitis, commenting on the fact that the serous surface of the peritoneum covers an area of 1.7 square meters and yet it does not absorb bacteria, when inflamed, while tendon sheaths and joints take up bacteria in swarms and pour them into the blood. It can not be a mere coincidence that Kanon, Libmann and Bertelsmann found no bacteria in the blood in fully 100 cases of intense peritonitis. The collapse can not be due to the bacteria but merely to the toxins; they are responsible for the local injuries, the paralysis of the bowel and the tympany. The toxins act on the vasomotors in the splanchnic region, paralyzing them until the organism becomes exsanguinated by the pouring of all the blood into the abdominal vessels. The heart fails because it has nothing to pump, and death is the result of the paralysis of the vasomotor center and not of paralysis of the heart. This is of immense importance in treatment, as saline infusion will start up the heart and force along the blood stagnating in the splanchnic region. Before the operation a saline infusion should be made as a preventive measure; otherwise the opening of the abdomen releases the paralyzed vessels of the splanchnic region from pressure, allowing them to suck up the rest of the blood which has been keeping the patient alive. This is the cause of the "peritoneal collapse." Bertelsmann is convinced that the patient can be tided past the stage of collapse in almost every case of peritonitis by intravenous infusion of from 3 to 4 quarts of salt solution with or without 7 drops of adrenalin. The saline infusion permits longer operations. In 72 cases of severe peritonitis in the last five years, 80 per cent. of the patients recovered under treatment along these lines, the operation concluded by stimulating peristalsis with enemas and local heat, finishing with lavage of the stomach if necessary.

95. **Treatment of Trigeminal Neuralgia.**—Fuchs has obtained good results in 16 cases of exceptionally severe trigeminal

neuralgia and also in 100 moderate cases by treatment with aconitin and vigorous purgation. The aconitin seems to have actual specific efficacy in trigeminal neuralgia. He prefers to give it in the form of eight or ten pills containing a maximum of 0.002 gm. for the daily dose. It is supplemented with calomel, 15 grains in ten doses in ten hours (0.1 gm. per dose), continuing afterward with a laxative water three times a day. In giving the aconitin he inquires constantly for signs of intoxication, paresthesia in tongue, lips or hands, mostly in the ulnar region, but has never observed anything of the kind, probably on account of the vigorous purgation which he regards as the greatest advance in the treatment of neuralgia in the last quarter century. In 14 of the above 16 cases the neuralgia had recurred after peripheral resection. The pain is probably of central origin in certain cases which explains the inefficiency of treatment, even of gasserectomy. On the other hand, peripheral resection and injections may induce temporary benefit.

Münchener medizinische Wochenschrift

102. **Mobilization of the Thorax.**—This communication from Bier's clinic at Berlin calls attention to the importance of mobilizing the thoracic vertebræ in attempts to expand and mobilize the chest. This element in the mobilization has been rather overlooked hitherto; the purpose is admirably accomplished by Klapp's creeping exercises. This method was described in THE JOURNAL, Feb. 1, 1908, page 410, as giving good results in scoliosis. It answered the same purpose as Freund's chondrotomy to mobilize the superior aperture as a means of influencing apical processes. The creeping method is deserving of wide application outside of the treatment of scoliosis. The exercise found most effectual for mobilizing the thoracic vertebræ starts with lordosis, the attitude similar to that of a creeping tiger or dachshund. The patient kneels, the thighs perpendicular, the elbows bent so that the arms imitate the bow-leg position of the dachshund while the head is bent far back. The pelvis is thus above the shoulders and the thoracic portion of the spine is in lordosis; this position must be maintained during the creeping. The arm is advanced and stretched before the hand touches the floor. This hand then turns and the elbow is bent as the trunk is advanced until the upper arm forms a right angle with the trunk. The arm thus forms the axis over which the thoracic vertebræ are levered by the drawing forward of the other arm, the scapula of the supporting arm forming the fulcrum of the lever. This exercise loosens up the thoracic vertebræ and spreads the ribs apart, and corrects torsion of the spine if present. The thorax expands more, the more correctly the lordosis of the thoracic vertebræ is localized during the sideward bend. The expansion of the chest under the influence of this creeping exercise can be followed with the *x*-rays. A number of such skiagrams are to be published in the transactions of the recent congress of orthopedic surgery at Berlin. The expansion of the chest provides better conditions for the large vessels and lungs, and is an important aid in the prophylaxis of disturbances in the circulation and of tuberculous apical processes.

103. **Local Cutaneous Reaction to Atoxyl.**—Moro noticed a local reaction in children injected with atoxyl; it resembled the cutaneous tuberculin reaction and paralleled it in 82 per cent. of the positive and 85 per cent. of the negative primary reactions to this Pirquet test. Repeated injection gave a more intensive and more rapid reaction than the first in 6 of 13 children injected several times. The other 58 children were given only a single injection.

105. **The Ocular Typhoid Reaction.**—Beckers reports application of Chantemesse's ocular typhoid toxin reaction in 30 patients with various affections and 8 typhoid patients. The instillation of a minute drop of typhoid toxin caused no reaction in 30 non-typhoid patients and none in the healthy, but there was a specific reaction in 7 of the 8 typhoid patients and in 6 out of 9 typhoid convalescents. These experiences confirm the specific importance of the test when applied with minute amounts; he does not use more than half the dose that Chantemesse recommends.

106. **Antiferment Treatment of Suppurative Processes.**—This communication from Garré's clinic at Bonn lauds the antiferment treatment of abscesses as a valuable measure. The principles were described in THE JOURNAL, Feb. 6, 1909, page 516. Müller's discovery of the proteolytic ferment in the leucocytes showed that the latter and their enzymes have an injurious action in an abscess; the excess of ferment breaks down the tissues, doing more harm than the bacteria themselves. The incision evacuating this excess of ferment acts as effectually as the antiferment which neutralizes the ferment, but the latter penetrates into the abscess walls, *protecting* the already infiltrated tissue from destruction by the leucocyte ferment while the defensive forces of the body attend to the destruction of the bacteria. The antiferment treatment thus protects the leucocytes from autolysis and protects the tissues from heterolysis by the leucocytes. The aim in tuberculous processes is just the reverse; here there is deficiency of the ferment, and the indication is to supply it from without. Trypsin has been used for the purpose as it is so closely allied to the leucocyte ferment and so readily obtainable. For the antiferment, Garré found that hydrocele fluid answered the purpose admirably. The results of this method of treatment are immediate arrest of the secretion, confirming the fact that the free ferment is the irritation that kept up the secretion. This, he asserts, causes us to revise our views in regard to laudable pus. Kantorowicz gives several examples of the effect in localized abscesses. In mastitis, furuncles and phlegmons the results were disappointing as the indispensable condition—direct contact between the living ferment and the antiferment—can not always be realized in these cases. The trypsin injections in the cold abscesses answered the desired purpose except in bone processes. The trypsin is indifferent to bone, and consequently chemotactic iodoform is more efficient than trypsin in bone lesions. The trypsin also proved effectual in cleaning up wounds; necrotic scraps were thrown off more rapidly, but this effect was observed only in the drier forms, never when there was much suppuration. The whole antiferment conception modifies previous views in regard to suppuration in many points, he adds, but the success of the treatment under proper conditions will convert the most skeptical.

113 *Permeability of Renal Filter. (Dichtigkeit des Nierenfilters.) J. Brodzki.
114 *Anesthetic and Antiphlogistic Action of Guaiacol. Hecht.
115 Successful Conservative Treatment of Extreme Prolapse of Rectum. (Ueber einen konservativ behandelten Fall von hochgradigem Mastdarmvorfall.) K. Bieling.

109. **Acute Perisigmoiditis.**—Strauss relates some case-histories of acute inflammation of the serosa of the sigmoid flexure, the syndrome having as great clinical importance, notwithstanding its rarity, as perityphlitis, which it much resembles. The anamnesis is of importance, especially a history of chronic diarrheic conditions and signs of ulcerative colitis; also a tendency to coprostasis, especially when alternating with diarrhea. Differentiation is important for treatment as the chief indication is to empty the colon and cure the pre-

existing ulcerative colitis if such exists; otherwise the main reliance is on strict bed rest, light fluid diet and local application of ice and morphin. Surgical intervention is not so promptly necessary as in an appendicitic process, at least in the endogenous cases, as a rule. In two such cases on record, the acute endogenous exudative perisigmoiditis healed after perforation into the intestine, but in one of his fatal cases peritonitis followed the perforation. In considering the indications it must be borne in mind that in the majority of cases the disturbance is secondary to appendicitis.

111. **Coffee in Production of Uric Acid.**—Besser relates research which confirms the fact that part of the caffein and theobromin is eliminated as uric acid, and consequently that coffee must be included in the purin-containing substances injurious in the diet of the gouty.

113. **The Permeability of the Renal Filter.**—Brodzki expatiates on the importance of throwing light on dietetic questions by pathologic experiments in order to obtain data for applying dietetic factors from a therapeutic point of view. For this purpose he has been giving 20 or 25 gm. (from 300 to 375 grs.) milk sugar in water in the morning in forty cases of various kidney affections, keeping this up for ten or fourteen weeks. In the cases with a tendency to much albuminuria the amount of urine increased and the edema and albuminuria became reduced, which he ascribes to the influence of the milk sugar in great measure. There was little, if any, increase in the reducing property of the urine in these cases, but in the others with only moderate glycosuria the reducing property rapidly increased. In a few cases of stationary contracted kidney the increase in the specific gravity was evidently also a result of the milk sugar.

114. **Guaiacol as an Anesthetic and Antiphlogistic.**—Hecht regrets that guaiacol is not used more for external application as its properties deserve. He reviews its history in local treatment of neuralgia, neuritis, gout, chronic rheumatism and traumatism, in the form of a salve, and for application to the surface of the chest in lung, pleura and febrile affections. He advocates a 10 per cent. solution or salve and reports excellent results from it in various cutaneous lesions, including erysipelas, furuncles and herpes zoster. There are no untoward by-effects unless too large doses are used, over 1.5 or 3 gm. (22.5 or 45 grs.).

121 Importance of Rhinology and Laryngology for Internal Medicine. (Bedeutung der Rhinologie und Laryngologie für die interne Diagnostik und Therapie.) E. Glas.

116. **Anaphylactic Seroreaction with Cancer.**—Pfeiffer and Finsterer confirm the constant occurrence of the anaphylactic drop in the temperature in their experimental research, and report further experiments with guinea-pigs treated with carcinoma juice. The results show that in the course of a cancer antibodies develop which induce anaphylaxis when injected into guinea-pigs. Guinea-pigs untreated or previously treated with normal human serum show no signs of anaphylaxis when injected with juice from carcinoma tissue. On the other hand, guinea-pigs injected forty-eight hours before with serum from the cancer patient and then injected with the cancer juice display severe anaphylactic symptoms, among others, the characteristic and easily measured anaphylactic drop in temperature. The anaphylactic shock occurs not only with the serum of the cancer patient from whom the juice was derived, but also with serum from other carcinoma patients. The serum in cancer cases, therefore, is distinguished from normal serum by the presence of anaphylactic antibodies. This antibody injected into the peritoneum of the guinea-pig transmits a passive anaphylaxis demonstrated in the drop of temperature when cancer juice is injected, which may prove to have differential value. The discovery of this anaphylactic property in a patient with tumor confirms the diagnosis of malignant disease. If the anaphylactic condition permanently vanishes after removal of the tumor the cure may be regarded as definite. Reappearance of the anaphylactic antibody should be an indication for renewed intervention. It is possible that the discovery of this antibody may throw light on the nature of cancer. The hypersusceptibility revealed by the presence of an anaphylactic antibody explains the unrestricted growth of the tumor and the possibility of metastasis—not only the serum but all the cells and tissues become hypersusceptible while the lack of this with benign tumors explains their inability to spread. If these premises are correct, the aim in treatment of cancer must be to put an end to the anaphylactic condition. This would prevent the spread of the malignant disease and influence the cancer without surgical intervention.

117. **Seven Years' Observation of 1,000 Soldiers After the Tuberculin Test.**—Franz reports the subcutaneous tuberculin test applied to a thousand recruits during 1902; the Hungarians gave 38.7 per cent. positive responses and the Bosnians from 61 to 76 per cent. None but the more robust was tested and only a small proportion of those giving a positive response have shown any signs of tuberculosis during the years since, only 46 during the first three years and 18 in the fourth; a total of 64 cases of clinical tuberculosis in 575 responding positively out of 1,002 tested. His experience further shows that the test with 0.003 gm. of tuberculin is not enough to reveal a latent tuberculous process in many cases by subcutaneous application. He is convinced that if he had used 0.01 gm. he would have obtained as many positive findings as Naegeli obtained in cadavers.

118. **Porges Precipitation Reaction in Syphilis.**—Schwarzwald has applied this test in 302 cases of syphilis with 22 controls and commends it as a simple and easy technic for differentiation in dubious cases. He used 0.5 per cent. solution of sodium glycocholate and advocates this test first and the Wassermann test only when the first gives a negative response.

120. **Transient Painful Infantile Pseudoparalysis.**—Turnowsky has encountered six cases of this affection during the last fifteen years. The children were from 15 months to 4 years old and the paralysis of the leg and arm came on suddenly with severe pain but no fever. The child dragged the limb and screamed when it was touched. The paralysis vanished in from one to five days as suddenly as it came on, but recurred three times in the course of a month or six weeks in 2 cases. He reviews the literature on the subject with the conflicting views in regard to the origin of the trouble; he explains it as a sudden slight dislocation in a joint by some abrupt movement, the dislocation being too slight to be detected by external examination.

123. **Pathology and Therapeutics of the "Vegetative" Nervous System.**—The Journal, Oct. 24, 1908, page 1475, mentioned previous research by Eppinger on the opposite pharmacologic action of certain drugs on different individuals. Certain persons are susceptible to the action of pilocarpin and atropin, both of which act on the vagus sustem, the former stimulating, the other inhibiting it, while other persons are susceptible

to adrenalin which acts on the sympathetic nervous system. To date no drug is known which has an inhibiting influence exclusively on the sympathetic system, similar to the inhibiting action of atropin on the vagus. By testing the action of pilocarpin and atropin and adrenalin it is possible to obtain an insight into the functioning of organs innervated by the vagus or sympathetic systems and Eppinger reviews the findings in a number of morbid conditions such as paroxysmal tachycardia, digestive reflex neuroses, Gowers' vasovagal attacks, etc. He cites two examples to show how in "vagotonic" individuals 0.0075 gm. of pilocarpin injected subcutaneously induces intense salivation, sweating and lachrymation with redness of face and neck, and 0.00075 gm. atropin sends the pulse from 80 up to 138, while 0.0075 gm. adrenalin fails to induce its usual effect of glycosuria and polyuria. In two examples of the "sympathecotonic" type, 0.01 gm. of pilocarpin and 0.001 gm. of atropin had no influence on saliva, sweat, tear secretion or pulse, but 0.001 gm. adrenalin induced pronounced glycosuria (7.93 gm. in the twenty-four hours' urine) and the amount of urine increased from 1200 to 2300 c.c. and from 1200 to 2800 c.c. In neuroses of the vagus minute amounts of "vagotropic" drugs have a marked therapeutic influence. In all his experience he has never found an individual who presented a pronounced reaction both to pilocarpin and to adrenalin. The "vagotonic" are more numerous among the young while with increasing age the "sympathecotonic" type predominates. Exophthalmic goiter is studied in detail from the standpoint of these pharmacologic functional tests, showing the difference in the symptoms and therapeutic response accordingly as the individual is vagotonic or sympathecotonic.

125. **Secreting Function of the Pancreas and Its Importance for Diagnosis.**—This communication relates functional tests of the pancreas undertaken with eighty patients with various affections. The patients drank 150 c.c. of oil, or 250 gm. of cream, fasting in the morning and sat still for forty-five minutes, after which the stomach content was siphoned out. In 43 of the 80 cases trypsin was found directly in the stomach content and in 29 others after the excess of acid had been neutralized with magnesia. In only 8 of the total number was there no trace of trypsin to be detected; these were patients with inoperable gastric cancer, diabetes, pernicious anemia or some severe liver affection. The smallest proportions of trypsin were found in patients with these affections or catarrh of the small intestine, cholelithiasis or diabetes insipidus. The largest proportions were in patients with little if any free hydrochloric acid in the stomach content. The trypsin was always in the activated form, showing that it had been mixed with intestinal juice. The test is more instructive when a series of examinations are made, constant absence of minute proportions of trypsin suggesting severe functional disturbance in the pancreas, while large amounts exclude such. The oil or cream breakfast also allows insight into the functioning of the liver from the proportion of bile found in the stomach content, and it reveals the admixture of intestinal juice and trypsin and thus explains anacid conditions. The presence of trypsin also is an index of the motor functioning of this part of the digestive tract. The research related shows further the importance of excluding fat from the test breakfast when examining merely for the chemical and motor functioning of the stomach.

126. **Action of Fever on Course of Infections.**—Barankeieff induced fever in rabbits by puncture of a heat center and then inoculated them with some mildly infectious agent, the results demonstrating that fever reduces materially the resisting power of the organism so that it yields to invasion and proliferation of bacteria of greatly attenuated virulence. It also reduces the immunity possessed naturally by rabbits against certain germs and the febrile organism also displays an exceptional tendency to autoinfection.

129. **Auscultation of Bronchial Respiration Over the Thorax as Sign of Mediastinal Lesion.**—D'Amato reports three cases of solid tumors in the mediastinum and five of aneurism or other lesion in which bronchial respiration was heard not only over the manubrium but over the body of the sternum and at times over the heart region, but less distinct. It was also heard diffuse over the clavicles, and most pronounced over the spine, even with tranquil breathing, with a much louder tone and over a much wider area than in normal conditions. In one case of solid tumor the bronchial respiration was heard over both the anterior chest walls. The positive auscultation findings over the spine with these mediastinal lesions has considerable differential importance both for children and for adults; the greatest intensity of the respiration sound is directly over the spine, not in the scapulovertebral line. Such findings in the apparently healthy do not disprove their differential importance as there may be some unsuspected lesion in the peribronchial glands, possibly long healed over. The positive findings are not constant with all mediastinal tumors, etc., but depend on their location and the consequent displacement of the trachea and bronchi.

133 *Ligation of Veins for Suppurative Portal Thrombosis after Appendicitis. Wilms.

132. **Operative Treatment of Femoral Hernia.**—Abrashanoff ties a long silk suture thread around the neck of the hernial sac after it has been emptied and draws each end of the thread out through the abdominal wall about three-quarters of an inch above Poupart's ligament, the distance between the emerging points of the ends of the thread being from one-half to three-quarters of an inch. Poupart's ligament is them drawn up and back to expose the posterior margin of the horizontal branch of the os pubis, and each end of the thread is passed through the triangular ligament. As the ends of the threads are then tied together, the hernial sac is drawn up tight and the peritoneum is also stretched, while the abdominal wall is drawn down to the os pubis on which Poupart's ligament rests. By this means the femoral canal is practically obliterated throughout its entire length. He has performed this operation in eight cases and commends it as effectual and stable. The technic is shown in three illustrations.

133. **Ligation of Veins in Suppurative Thrombosis of the Portal Vein.**—Wilms tied off the veins in the mesentery connected with the cecum and appendix and was surprised to find that all the serious symptoms were arrested at once and the patient rapidly recovered. The principle is the same as for ligation of the ovarian veins in puerperal pyemia, but in suppurative portal thrombosis the danger of metastasis in the liver is especially imminent. He is not aware of a single instance of spontaneous recovery in such cases with recurring rigors. All his patients with this syndrome succumbed, but it is becoming less frequent now that early operations in appendicitis forestall the development of the venous thrombosis. In his case an abscess in the region of the cecum in a man of 42 had developed in the course of ten days and chills occurred daily after evacuation, with temperature over 104 the fourth day. In the triangle formed by the junction of colon and cecum two small arteries were tied separately and the veins ligated in two bunches, the line of ligation forming the hypothenuse of a triangle of which the junction of colon and cecum formed the other two sides. The temperature dropped at once and no further chills were observed while the circulation in the intestines showed no signs of disturbance and stool was passed the next day. The operation is effectual only before infectious emboli have reached the liver; the chills may indicate merely toxic action. Even if a few bacteria have entered the circulation the organism in many cases is able to cope with them. It does not succumb until its power of producing antitoxins has become exhausted.

140 [illegible] Cystomas Removed without Interfering with Pregnancy. T. Petri.

138. **Mishaps with Spinal Anesthesia.**—Risch reports from Franqué's clinic at Giessen four threatening mishaps with spinal anesthesia out of the 315 cases in which this method has been employed since 1908. Two of the patients, women, were finally revived but the other two succumbed. In the first there was complete arrest of the respiration and in the second heart collapse, while in the fatal cases the heart action stopped abruptly and permanently. The women in these fatal cases were obese and had lost much blood; the heart in one was flabby and inclined to fatty degeneration while the cardiovascular system in the other seemed to be sound except for slight arteriosclerosis. The experiences at this clinic with spinal anesthesia in 14 cases of Cesarean section were gratifying, but the mishaps have convinced Franqué that spinal anesthesia must be restricted to certain specially adapted cases, and that complications on the part of the vascular system or anemia practically contraindicate it. Bier's latest report on spinal anesthesia states that we must reckon with one death to each 400 or 500 spinal anesthesias.

139. **Suprarenal Preparations in Gynecology and Spinal Anesthesia.**—The communications by Neu and Braun are in reply to the report of two fatalities mentioned in THE JOURNAL, July 31, page 423. Both insist that the suprarenal preparations should be used very much diluted as this reduces materially the toxic action even of the same dose. Neu further urges cautious estimation of the individual reaction in the given case and especially the exact state of the heart and vessels. He warns decidedly against intravenous injection, and emphasizes the necessity for extreme care in injecting the preparation where it might get into a vein. Braun insists that the vaginal portion of the uterus can be rendered anemic effectually and safely by injection of only 10 c.c. of 200 c.c. of salt solution containing merely 1 c.c. of the 1 per thousand solution of suprarenin—there is no need to use a stronger concentration.

146. **Acquired Heart Disease in Children.**—Forssner reports the ultimate outcome in 96 cases of heart disease, articular rheumatism and chorea in children, investigated from fifteen to twenty-two years later, out of a total of 116 cases. All this material is classified and tabulated under various headings, the long course of observation permitting several important conclusions. Acute pericarditis seems to develop very rarely in acute articular rheumatism if it does not make its appearance in the first few months. In 10 out of 11 cases of acute pericarditis at the beginning of the rheumatic affection, the heart was previously sound. In the 16 cases of acute pericarditis 2 of the patients died during the first attack and 9 after a subacute or chronic course, up to fifteen years in one instance. One patient recovered completely and the heart has been apparently sound for twenty-nine years since. In another group of 25 cases of a mild heart affection not one of the patients re-examined lately had completely normal heart. The trouble had been slight mitral insufficiency, free from pleural or lung complications which were frequent in the first group. In the 56 cases of articular rheumatism in children, no less than 31 have died of some heart affection, and 4 still present some severe cardiac defect; in 4 others a similar defect has developed since; in 5 a mild cardiac defect is manifest and in 5 others it is probable. In only 5 is the heart apparently normal at present. The prognosis of articular rheumatism in this respect seems to depend on whether a heart affection develops within the first few months or not. If complications on the part of the heart develop later they seem to be of a milder form. Only 4 of the 24 patients with chorea minor have succumbed to heart disease and only 2 present a serious cardiac defect, 6 a mild one and in 7 the heart findings are apparently normal, while 2 have died of tuberculosis. In the 9 cases in which the children have had both chorea and acute articular rheumatism, 4 died of some heart affection, 2 have still a serious and 1 a slight cardiac defect, and one patient is apparently sound while another with objective findings is yet subjectively well.

PRESERVATIVES IN FOOD MATERIALS

THEIR DETECTION AND EFFECT *

D. H. BERGEY, M.D.
Assistant Professor of Bacteriology, University of Pennsylvania
PHILADELPHIA

The use of preservatives in food materials has engaged the attention of sanitarians for a number of years and they have uniformly condemned the practice. Nevertheless new and hitherto unsuspected uses of preservatives are discovered from time to time notwithstanding the laws prohibiting their use.

The plea of the manufacturers is that the use of preservatives is absolutely necessary to keep the food materials, and also that it is not harmful.

During the past ten years nearly all of the states of the union have enacted laws which aim to prohibit the use of food preservatives. The national law of 1906 has served as a model for many of the state laws enacted since that time.

The Food and Drugs Act, passed by Congress and approved June 30, 1906, provides "for preventing the manufacture, sale, or transportation of adulterated or misbranded or poisonous or deleterious foods, drugs, medicines, and liquors, and for regulating traffic therein, and for other purposes."

Section 7 of the act states that a food shall be deemed to be adulterated:

First: If any substance has been mixed and packed with it so as to reduce or lower or injuriously affect its quality or strength.

Second: If any substance has been substituted wholly or in part for the article.

Third: If any valuable constituent of the article has been wholly or in part abstracted.

Fourth: If it is mixed, colored, powdered, coated, or stained in a manner whereby damage or inferiority is concealed.

Fifth: If it contain any added poisonous or other added deleterious ingredient which may render such article injurious to health: *Provided*, That when in the preparation of food products for shipment they are preserved by an external application applied in such a manner that the preservative is necessarily removed mechanically, or by maceration in water, or otherwise, and directions for the removal of said preservative shall be printed on the covering or the package, the provisions of this act shall be construed as applying only when said products are ready for consumption.

Sixth: If it consists in whole or in part of a filthy, decomposed, or putrid animal or vegetable substance, or any portion of an animal unfit for food, whether manufactured or not, or if it is the product of a diseased animal, or one that has died otherwise than by slaughter.

Regulation 12 explains the terms "coloring," "powdering," "coating," and "staining" as used in Section 7:

(a) Only harmless colors may be used in food products.

(b) The reduction of a substance to a powder to conceal inferiority in character is prohibited.

(c) The term "powdered" means the application of any powdered substance to the exterior portion of articles of food, or the reduction of a substance to a powder.

(d) The term "coated" means the application of any substance to the exterior portion of a food product.

(e) The term "stain" includes any change produced by the addition of any substance to the exterior portion of foods which in any way alters their natural tint.

Regulation 14 relates to the external application of preservatives:

(a) Poisonous or deleterious preservatives shall only be applied externally, and they and the food products shall be of a character which shall not permit the permeation of any of the preservative to the interior, or any portion of the interior, of the product.

(b) When these products are ready for consumption, if any portion of the added preservative shall have penetrated the food product, then the proviso of Section 7, paragraph 5, under "Foods," shall not obtain, and such food products shall then be subject to the regulations for food products in general.

(c) The preservatives applied must be of such a character that, until removed, the food products are inedible.

Regulation 15 relates to the wholesomeness of colors and preservatives:

(a) Respecting the wholesomeness of colors, preservatives, and other substances which are added to foods, the Secretary of Agriculture shall determine from chemical or other examination, under the authority of the agricultural appropriation act (Public 382, approved June 30, 1906), the names of those substances permitted or inhibited in food products; and such findings, when approved by the Secretary of the Treasury and the Secretary of Commerce and Labor, shall become a part of these regulations.

(b) The Secretary of Agriculture shall determine from time to time, in accordance with the authority conferred by the agricultural appropriation act (Public 382, approved June 30, 1906), the principles which shall guide the use of colors, preservatives, and other substances added to foods; and when concurred in by the Secretary of the Treasury and the Secretary of Commerce and Labor, the principles so established shall become a part of these regulations.

Food Inspection Decision 100, approved by Secretary Wilson Dec. 9, 1908, states:

In view of the extent of the bleaching process (flour bleached with nitrogen peroxid) and of the immense quantity of bleached flour now on hand or in process of manufacture, no prosecutions will be recommended by this Department for the manufacture and sale thereof in the District of Columbia or the territories or for transportation or sale in interstate or foreign commerce, for a period of six months from the date thereof.

Food Inspection Decision 101, approved by Secretary Wilson Dec. 18, 1908, states:

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

> Benzoate of soda, in quantities not exceeding one-tenth of 1 per cent., may be added to those foods in which generally heretofore it has been used. The addition of benzoate of soda shall be plainly stated on the label of each package of such food.

Food Inspection Decision 102, dated Dec. 23, 1908, states:

> Until further notice, vegetables greened with copper and which are otherwise suitable for food, will be allowed entry into the United States, if the label bears the statement that sulphate of copper or other copper salts have been used to color the vegetables.

The "pure food" laws of the following states conform in all important particulars to the national laws: Vermont, 1908; Massachusetts, 1908; Connecticut, 1907; New Jersey, 1908; Pennsylvania, 1909; Delaware, 1907; Virginia, 1908; West Virginia, 1907; North Carolina, 1907; Georgia, 1906; Kentucky, 1908; Tennessee, 1907; Illinois, 1907; Arkansas, Colorado, 1907; Texas, 1909; Oklahoma, 1909.

Food Inspection Decision 101 permits the use of one-tenth of one per cent. of sodium benzoate in "those foods in which generally heretofore it has been used." This provision is apparently so drawn as to make it permissible to use sodium benzoate in almost any food substance. Some of the states which permit the use of sodium benzoate restrict its use to certain substances, as catsup, etc., while others have even less definite restrictions than those of the United States law.

Aside from the food regulations of the United States, the laws of the following states permit the use of sodium benzoate in food: Maine, New Hampshire, Pennsylvania, North Carolina, Georgia, Iowa, Texas, North Dakota, South Dakota, Wyoming, Oregon, and Washington. In the laws of the other states sodium benzoate is not expressly mentioned, but the laws of most of the states appear to prohibit its use.

The use of benzoate of soda, permitted by Decision 101, is, to my view, an unmitigated evil since we have the assurance of many manufacturers that such use is absolutely unnecessary to preserve the food materials in which it is used.

Dr. H. W. Wiley, chief of the Bureau of Chemistry, United States Department of Agriculture, in Circular 39 of that department, gives the results of experiments and the general conclusions drawn from them as to the injurious effects of sodium benzoate, as follows:

> From a careful study of the data in the individual cases and of the summaries of the results, it is evident that the administration of benzoic acid, either as such or in the form of benzoate of soda, is highly objectionable and produces a very serious disturbance of the metabolic functions, attended with injury to digestion and health.
>
> As in the case of boric acid, salicylic acid, and sulphurous acid, this injury manifests itself in a number of different ways, both in the production of unfavorable symptoms and in the disturbance of metabolism. These injurious effects are evident in the medical and clinical data, which show great disturbances of digestion, attended by phenomena which are clearly indicative of irritation, nausea, headache, and, in a few cases, vomiting. These symptoms were not only well marked, but they were produced on healthy individuals, receiving good and nourishing food and living under proper sanitary conditions. It is not only fair to conclude, therefore, that under similar conditions of administration of benzoic acid or benzoate of soda in the case of weaker systems, or less resistant conditions of health, much more serious and lasting injury would be produced.
>
> It was also noticed that the administration of benzoic acid and benzoate of soda was attended with a distinct loss of weight, indicative of either a disturbance of assimilation or an increased activity in those processes of the body which result in destruction of tissue. The production of a loss of weight in cases of this kind must be regarded as indicative of injurious effects.
>
> The influence of the benzoic acid and benzoate of soda on metabolism was never of a character indicative of a favorable change therein. While often the metabolic changes were not strongly marked, such changes as were established were of an injurious nature. It is evident that the administration of these bodies, therefore, in the food tends to derange metabolism in an injurious way.
>
> An important fact in connection with the administration of these bodies is found in the efforts which Nature makes to eliminate them from the system. In so far as possible the benzoic acid is converted into hippuric acid. There is a tendency usually manifested, however, to retain the benzoic acid in the body for a notable length of time, and this is much more marked in the case of benzoate of soda than in the case of benzoic acid.
>
> While the administration of both of these bodies, therefore, is undoubtedly harmful, the injurious effects are pronounced more rapidly in the case of benzoic acid than they are in the case of benzoate of soda; the data, however, will show that the total harmful effect produced in the end is practically the same in both cases; hence there appears to be no reason for supposing that the administration of the preservative in the form of benzoate of soda can be justified by an argument relating to the less injurious effect thereof on health.
>
> The occurrence of microscopic bodies in the urine is undoubtedly increased under the administration of benzoic acid in both forms, thus showing conclusively the tendency to stimulate the destructive activities of the body.
>
> Coming to final consideration of all of these different phases of the subject, there is only one conclusion to be drawn from the data which have been presented, and that is that in the interests of health both benzoic acid and benzoate of soda should be excluded from food products. This conclusion is reached independently of any consideration of the conditions which it is alleged surround the processes of manufacture and which result in the demands of the manufacturers to be allowed to continue the use of these substances. This is a subject which must be discussed from an entirely different point of view and has no bearing whatever on the general conclusions which have been reached, namely, that both benzoic acid and benzoate of soda are bodies which, when added to foods, are injurious to health.

In view of the fact that benzoic acid and sodium benzoate are allowed by the national and state laws, I hoped to perfect a speedy and simple method of discovering these substances in food substances.

ANTIFERMENTATIVE TEST FOR THE PRESENCE OF PRESERVATIVES IN FOOD MATERIALS

I have made a large series of tests to ascertain with what degree of certainty the presence of preservatives may be detected in food by means of the antifermentative action of the preservatives on trypsin. The studies of Bliss and Novy[1] show that of the ordinary digestive ferments trypsin is injured to the greatest extent by formaldehyd, aside from the effect of the preservative on the food constituents themselves. These results are confirmed by those of Sheperd,[2] who found that nitrous acid affected pancreatic digestion in higher dilution than it did the other ferments which he employed. For these reasons I regarded trypsin as a delicate indication of the presence of preservatives in food.

The tests for the detection of preservatives in food were carried out by the addition of small amounts of the food to a definite volume of a sterile solution of casein and determining the inhibiting influence of the preserved food on the tryptic digestion of the casein by the addition of a few drops of an alcoholic solution of acetic acid to the mixture at the end of a period of digestive action.

---

[1] Bliss and Novy: Jour. Exper. Med., 1899, iv, 47.

[2] Sheperd: Report of Food and Dairy Commissioner, North Dakota, 1908.

The following experiments may be cited as indicative of the results obtained in a large series of tests:

TABLE OF RESULTS

Thirteen test-tubes containing 2 c.c. casein solution and 0.5 c.c. trypsin solution, to which increasing quantities of milk serum were added and decreasing quantities of 0.85 per cent sodium chlorid solution. These tubes were incubated at 37.0 degrees C. for three-quarters of an hour, when the alcoholic acetic acid was added drop by drop, about six drops of the acetic acid to each tube:

Milk Serum.	NaCl.	Sodium Benzoate.	Sodium Sulphite.	Results.
0.0 c.c.	1.0 c.c.	......	......	Nearly complete digestion
0.1 c.c.	0.9 c.c.	......	......	Nearly complete digestion
0.2 c.c.	0.8 c.c.	......	......	Nearly complete digestion
0.3 c.c.	0.7 c.c.	......	......	Nearly complete digestion
0.4 c.c.	0.6 c.c.	......	......	Slight precipitate formed
0.5 c.c.	0.5 c.c.	......	......	Slight precipitate formed
0.6 c.c.	0.4 c.c.	......	......	Definite precipitate formed
0.7 c.c.	0.3 c.c.	......	......	Definite precipitate formed
0.8 c.c.	0.2 c.c.	......	......	Definite precipitate formed
0.9 c.c.	0.1 c.c.	......	......	Definite precipitate formed
1.0 c.c.	0.0 c.c.	......	......	Marked precipitate formed
0.0 c.c.	0.5 c.c.	0.5 c.c.	......	Definite precipitate formed
0.0 c.c.	0.5 c.c.	......	0.5 c.c.	Slight precipitate formed

Increasing quantities of milk serum exerted an ascending effect in inhibiting the tryptic digestion of the casein, indicating that some preservative had been added to the milk. The addition of 0.5 c.c. sodium benzoate solution (concentrated) produced a slightly greater inhibition of the tryptic digestion than did an equal quantity of the milk serum, while 0.5 c.c. sodium sulphite solution (concentrated) produced approximately a degree of inhibition of the tryptic digestion equal to that produced by an equal quantity of the milk serum.

I have also attempted to ascertain the reliability of the antifermentative test in the detection of preservatives in meat. The hacked meat is placed in a meat-press and the blood and juices expressed. The main difficulty in applying the test to the meat juices lies in the fact that normal blood serum exerts an antifermentative effect. I have attempted to overcome this influence by heating the meat juice and recovering the watery part of the juice for the tests. The tests with this final product have not been satisfactory because, apparently, the major portion of the preservatives is retained in the coagulated albumin of the blood serum, and in consequence the tests made on the watery part of the meat juice were never very decisive.

The evidence which scientific investigators have collected all shows that the addition of chemical preservatives to food substances is injurious to the consumer in several different ways:

1. The use of preservatives permits the use of food substances that are of inferior grade or that are not perfectly fresh.
2. The food preservatives when taken into the body must be eliminated subsequently; this operation entails extra labor on some special organ or organs, and this extra labor will sooner or later lead to direct injury.
3. Many of the food preservatives are direct poisons and their constant ingestion induces chronic poisoning with its concomitant effects.
4. The food preservatives have an antifermentative effect on the different digestive ferments, especially on trypsin, and thus retard digestion and interfere with assimilation.
5. The food preservatives act on the food substances in such a manner as to render them less easily digested or even wholly indigestible, and make it necessary for the body to deal with partly digested food or deprive it altogether of nutrition, especially of nitrogenous food.
6. In consequence of the use of food preservatives digestion and assimilation are interfered with, and the general nutrition of the body suffers through organs that are overtaxed and injured in attempting to eliminate the poisonous chemical substances, and in attempting to deal with imperfectly split food substances that may be in such a state as to preclude their utilization, especially on account of the lack of digestive ferments, because of the loss entailed through the destructive action of the food preservatives.

SUMMARY

Contrary to my expectations the use of the antifermentative test for the detection of preservatives in foods does not give results that are satisfactory in every particular. The employment of this test must be carried out in such a manner as to eliminate normal antifermentative effects in the food substances, and attempts to remove these normal antiferments may lead to the simultaneous removal of the preservative.

In view of our knowledge of the detrimental effects of chemical food preservatives there is no more reprehensible practice than that of permitting their use in foods in any quantity whatever. The better class of manufacturers and dealers have set us an example, which we should follow, in the fight which they are making against the enactment of laws that in any particular permit the use of chemical substances for the preservation of foods where their use is not absolutely necessary.

We should not allow the greed of unscrupulous manufacturers and dealers to overrule our knowledge of the evil effects of the use of food preservatives. The medical profession owes it to itself to uphold the laudable position assumed by Dr. Wiley in his crusade against food adulteration, and any course which falls short of this will stultify the profession in the eyes of educated humanity of to-day and for all time to come.

THE PARASITOLOGY OF SYPHILIS [*]

FREDERICK G. HARRIS, M.D.
Professor of Dermatology, Illinois Post-Graduate Medical School; Adjunct Professor of Dermatology, College of Physicians and Surgeons, Medical Department, University of Illinois; Attending Physician, Cook County Hospital
CHICAGO

Syphilis has long been considered an infectious disease, but until recent years the discovery of the causal agent has eluded the most careful investigation. There has hardly been a pathologist or syphilographer of note who has not attempted to unravel the mystery. It would be impossible here to enumerate all the alleged causes that have been reported. Lassar has said that during the past twenty-five years at least 125 causes have been assigned to syphilis. It is evident that the great majority of these theories were very short-lived. There are three, however, that deserve mention. The bacillus which Lustgarten described in 1885 occupied the stage for several years, being defended by so good an observer as Weigert, but later it was shown to be identical with the smegma bacillus. The next appearance was Neissen's so-called syphilis bacillus. Recently Neissen[1] has published the results of his fifteen years' work in the form of an extensive atlas profusely illustrating the remarkable transformation of his organism from the vegetable to the animal kingdom and back again. It is remarkable with what persistence Neissen has pursued his phantom. His is a case of "love's labor lost," for his results have never been confirmed.

---

[*] Read in the Section on Dermatology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[1] Neissen: Der Syphilis Bacillus, Leipzig, 1908.

Somewhat on the same order has been the work of Siegel,[2] who, in 1905, described his *Cytorrhyctes luis* along with cultural and inoculation experiments. Siegel's work attracted a great deal of attention, and, while the majority of observers failed to confirm Siegel's findings, a few, notably Merk,[3] Freund[4] and Jancke,[5] did confirm them. As a court of last resort, Schaudinn was selected to pass judgment on the cytorrhyctes, which he did very shortly, failing to confirm Siegel's work and announcing his own discovery of the *Spirochæta pallida.*

At the present time there is probably no one who believes in the cytorrhyctes, except Siegel and his pupils, and they were until recently busily engaged in explaining the cytorrhyctes as one of the developmental stages of the *Spirochæta pallida.*

Schaudinn and Hoffman[6] announced their discovery in May, 1905; and it is remarkable with what unanimity confirmatory observations were reported from all quarters. The bibliography on the subject is already enormous.

The organism, as described by Schaudinn, is an extremely slender thread, closely wound in the form of a spiral similar to a corkscrew. In length it varies from 7 to 21 microns. The ends are pointed and provided with flagellæ. It stains with most of the anilin dyes, but only very faintly; the best staining method is probably that of Giemsa, which stains the organisms a pale red. In tissues the best method of staining is that of Levaditi.

There have been many attempts made to grow the spirochete on artificial media, but they have been uniformly successful. Recently Schereschewsky[7] has reported successful results. Levaditi and others have reported a seeming increase in the number of organisms when grown in collodion sacs in the peritoneal cavity of rabbits. They have also been obtained in pure culture after inoculation into the anterior chamber of the eye of rabbits and other animals.

This brings up the question of inoculation experiments. Metchnikoff and Roux,[8] in 1903, demonstrated the susceptibility of the anthropoid apes to syphilis. Haensell,[9] in 1881, and Klebs,[10] Siegel[11] and Schultz[12] had all reported successful inoculation experiments, but on account of the absence of secondary manifestations or subinoculations their results are doubtful.

At the present time, however, there are numerous observations showing the pathogenicity of the spirochete. Finger and Landsteiner inoculated monkeys with spirochetal material and transmitted the infection from animal to animal through forty-five different monkeys. Metchnikoff and Roux, Neisser,[13] Hoffman and Brüning,[14] Mühlens[15] and many others have made successful inoculations and recovered the spirochete.

Bertarelli[16] was the first to demonstrate the susceptibility of rabbits. His results have been confirmed by Scherber,[17] Greef and Clausen,[18] Kraus and Volk[19] and many others. Bertarelli and Tomasezewski[20] carried the spirochete from rabbit to rabbit, and later to monkeys and guinea-pigs.

Hoffman[21] and Brüning have obtained positive results in dogs. It seems probable that most of the lower animals are susceptible to inoculation with the spirochete; only the higher monkeys, however, show evidence of secondary syphilis, the lower animals reacting only by the production of a local lesion at the site of the inoculation. Neisser[22] has shown, by experiments on several hundreds of monkeys, that, in spite of the fact that the lower monkeys do not develop evidence of general syphilis, the virus is distributed throughout the body.

In the face of so much confirmatory evidence it would seem useless for any one to deny the specificity of the spirochete; and yet there have been many who have done so.

It is manifestly impossible for the spirochete to pass through a Pasteur filter; yet Jancke,[23] a pupil of Siegel's, reports a successful inoculation with syphilitic material which had been passed through a Berkefeld-Chamberlain filter. This is in direct contradiction to the results obtained by Klingmüller and Baermann,[24] Metchnikoff[25] and Siebert.[26] Since Jancke did not find any spirochetes, nor did he make any subsequent inoculation experiments, it is possible that from the syphilitic toxins injected he obtained a local syphilid, analogous to the toxic tuberculids obtained by Zieler,[27] von Pirquet and others.

Another short-lived objection to the spirochete theory was the question of the identity of the so-called silver spirochetes obtained by the Levaditi[28] method of staining. They were held to be nerve fibrillæ, cell borders, fibrin, etc. The introduction of the dark-ground illuminator effectively put an end to this controversy.

Neisser ably sums up the question of the specificity of the spirochete as follows:

> As long as we are not in a position to obtain the spirochete in pure culture, and with such a culture produce syphilis in the lower animals, the proof of the specificity of the *Spirochæta pallida* depends essentially on the demonstration of its constant presence in all syphilitic lesions and its constant absence in non-syphilitic lesions.

What are the facts in the case?

It may be said that the spirochete can be demonstrated in all chancres, and in their regional adenitis, and in all condylomata and mucous patches. Noeggerath and Staehelin[29] found them in the circulating blood. Rolshoven[30] found them in the blood in thirty out of forty cases; in one case, three weeks before the eruption. Hoffman[31] produced a successful inoculation of a monkey with blood from a man whose syphilis was of six months' duration and who had a profuse secondary syphilis. Bandi and Simonelli[32] obtained the organisms in the blood from a patch of secondary erythema. Veillon and Girard[33] found them in the capillaries of an erythematous patch. Jacquet and Sevin[34] found them in all secondary lesions. They have been found innumerable times in papular syphilids. Spitzer[35] found the organisms in a case of ulcerating syphilid of eight years' duration, also in a gumma of the scalp. Doutrelepont and Grouven[36] and Tomaszewski,[37] Schaudinn,[38] Hoffman, Neisser and many others have found the spirochete in gummata. They have been found by numerous observers in the placenta and umbilical cord. They are found in the great majority of cases of congenital syphilis and in all organs and tissues of that condition. Meyer[39] examined eighteen macerated non-syphilitic fetuses and failed to find any spirochetes.

They have been found many times in various internal organs in acquired syphilis; notably in the heart and blood vessels, especially in cases of aortitis and endarteritis, in the liver in syphilitic hepatitis, and in the kidneys in syphilitic nephritis. In spite of the increasing evidence of the syphilitic etiology of tabes and paresis, I have never heard of the *Spirochæta pallida* being found in the central nervous system in acquired syphilis. Gaucher and Merle[40] found the organisms in the cerebrospinal fluid of a patient with cerebral syphilis. Neisser[41] in a case of secondary syphilis found the spirochete in the spinal fluid. It is remarkable, however, how few observations there are on this subject.

To sum up, it may be said that the *Spirochæta pallida* has been found innumerable times in all the lesions of every stage of syphilis. In fact, the presence of the organism is the cause of the lesions. In studying these lesions one is struck with the marked variation in the number of organisms present. As a general rule, it may be said that the more acute the lesion the greater the number. The organisms, as a rule, occupy the intercellular lymph spaces, although it is not uncommon to find them within a cell. They are more numerous in the center of the lesion, diminishing toward the periphery, but extending even into the non-inflammatory area. A remarkable circumstance noticed by all observers is the vast number of organisms in congenital syphilis and the slight evidence of inflammatory change.

The discovery of the *Spirochæta pallida* has resulted in an entirely new pathogenesis for the disease. It has been found in the experimental work that the most successful method of inoculation is by rubbing the virus into a scarified area of the skin; this in addition to the fact that the genital region of animals is the most susceptible part of the body may account for the sexual transmission of the disease and the relatively small percentage of extragenital infections.

Given an inoculation, the infection for a time is purely local; during the period of incubation the virus proliferates until the irritation becomes sufficient to cause the tissues to react by the production of a local inflammatory area, which tends to necrosis, but undoubtedly may resolve. From this local focus a dissemination of the infecting organisms takes place, the most usual route being by way of the lymph channels, although there is no doubt that at times the dissemination is hematogenous. Wolters[42] and others have demonstrated sections of chancres showing the spirochete in the blood vessels. This opens up an interesting and important point, as to the time at which this dissemination occurs. There is not much doubt but that this varies within wide limits. Neisser[43] in a large series of experiments attempted to solve this question by excising the inoculated area at varying intervals of time. His results were not conclusive. He found that in six cases excision at periods from ten minutes to twelve days prevented dissemination; on the other hand, in ten other cases excision was useless, even when done as soon as eight to fourteen hours after inoculation.

In whatever manner and at whatever time dissemination takes place, it is eventually by means of the blood stream that the spirochetes are distributed throughout the body. They do not remain in the circulating blood, but locate in the tissues. They show a predilection for certain tissues and organs, notably the skin, lymphatic tissues, the circulatory system, glandular organs, and, as Neisser has shown, the bone-marrow. Wherever they locate they may cause an inflammatory reaction, which is more or less characteristic, aside from the spirochetal content.

From the results obtained by the Wassermann[44] reaction, it is evident that pathologic changes are much more frequent in the internal organs than we have heretofore suspected.

As dermatologists, we are particularly interested in the cutaneous localization of the spirochete. We no longer recognize a toxic syphilid; all the cutaneous manifestations of the disease represent foci of spirochetal growth in which the spirochetes may persist for long periods, and from which a new local or general dissemination may occur. This remarkable quality which the spirochetes possess of lying dormant for long periods, their presence seemingly causing no pathologic changes, accounts for many of the characteristic late secondary eruptions, such as the annular, circinate and corymbose syphilids.

This tendency of the infection to become latent accounts in part for the marked chronicity of the disease. Füresz[45] examined lesions from twenty-four cases to determine the effect of mercurial treatment on the presence of the spirochetes. In spite of the fact that the cases had from ten to fifty-five inunctions, spirochetes were found in seventeen cases. They could be found as long as the least grade of infiltration was present. In fact, the organisms have been found at the site of a previous eruption.

The question of immunity has taken on new life since the discovery of the spirochete. It has always seemed rather illogical that a syphilitic should be immune to heterogenous virus and not immune to his own virus. The experiments of Finger and Landsteiner and Neisser show that, strictly speaking, there is no immunity. The apparent immunity, such as expressed by Colles' and Profeta's law, has been shown by the results of the Wassermann reaction to be due to a latent syphilitic infection. This is also true of 47 to 57 per cent. of syphilitics after the usual treatment.

Admitting the etiologic rôle of the spirochete in syphilis, the question naturally arises: Of what value is the organism for diagnosis? Aside from the Wassermann reaction, the demonstration of the spirochete is the most reliable means at our disposal for the diagnosis of syphilis; as it is, these two factors give us practically absolute control of the diagnosis of syphilis in all its stages.

The greatest field for usefulness of the demonstration of the spirochete is in the diagnosis of primary syphilis; here it is far more reliable than the Wassermann reaction and much simpler. The spirochete can be demonstrated in every chancre and its contiguous enlarged lymphatic glands. I believe with Rona[46] that the finding of the spirochete permits a positive diagnosis to be made earlier than any other symptom. The Wassermann reaction in primary syphilis is not nearly so reliable and is infinitely more difficult of performance. The percentage of positive reactions increases in direct ratio to the duration of the infection; therefore the statistics of different observers vary greatly. When one considers the duration of the chancre, one finds that a positive Wassermann reaction is unusual before the third week, and that after that time the percentage of positive reactions increases up to the time of the general eruption, when it is practically 100.

Hoffman, Blumenthal and Roscher[47] all hold that in primary syphilis, diagnosis by means of the spirochete is simpler, quicker and more certain than the Wassermann reaction.

After the primary stage, the Wassermann reaction is so much more reliable that I have substituted it for the demonstration of the spirochete in doubtful cases.

The great drawback to the more widespread use of the demonstration of the spirochete for the diagnosis of primary syphilis has been the difficulty of staining the organism. Since the introduction of the Reichert dark-ground illuminator this is no longer a valid reason for the non-use of this most reliable means of diagnosis. By means of this instrument we are in a position to diagnose syphilis from the moment the initial lesion is first noticed. The method is so reliable, so simple and consumes so little time that there is no reason why it should not supplant all other methods of diagnosis.

As seen with the dark-ground illuminator the *Spirochæta pallida* is so characteristic that there is absolutely no difficulty in identifying it. The chief characteristics are as follows:

1. Size.—The spirochetes vary in length from 7 to 21 microns, being from one to three times the diameter of a red blood cell. It is not uncommon to see the organism longer than this, but I believe such forms to be composed of two or more individuals.

2. Shape.—They are seen to consist of an extremely slender thread closely wound in a corkscrew form, the windings being very acute. In fresh preparations the windings are absolutely regular, but as the specimen gets older the organism changes form, the most frequent change being an irregularity or obliteration of the windings in the central portion.

3. Position of Ends.—The ends of the pale spirochete are sharp and terminate on the periphery of the spiral and not in the center as in the other forms of spirochetes. This peculiarity is very characteristic, but is seen only when the organism rotates on its long axis.

4. Motility.—When the specimen is freshly prepared the organism is very active and possesses the following motions: (A) A rotation on its long axis in either direction; this motion is very rapid, but not necessarily accompanied by a change of position; as the specimen gets older this motion grows less. (B) It progresses from place to place, but not so rapidly as the other forms of spirochetes commonly met. (C) it has a quick and spasmodic bending or twisting motion. This form of movement increases as the specimen gets old, and at times one sees an organism bent in the form of a circle, resembling somewhat a crenated red blood corpuscle. It is not uncommon to find two organisms joined end to end. Again, one sees two or three organisms lying side by side.

The number of organisms found varies in the different lesions. They are most numerous in chancres, condylomata and mucous patches and vary from two or three in a field to sixty or eighty. Patients who have received some treatment show fewer organisms than the untreated ones. A few days' local treatment with calomel or other mercurial preparations causes a marked diminution in the number present in the chancre, although they are very numerous in the enlarged inguinal glands.

I have been using this method for two years and have never failed to find the organisms in chancres, mucous patches and condylomata. In our first communication,[48] Dr. Corbus and I reported finding the spirochete in mucous patches in three cases in which the syphilis was from one to three years old. Recently we found them in a mucous patch in which the infection was of eight and one-half years' duration. Neilsen[49] reports a case with a papulo-erosive syphilid of the mouth in which he demonstrated the spirochete nine years after the infection. Hoffman has reported a similar case and Papée[50] has reported one thirteen years after the initial lesion. These observations are important in view of the fact that some authorities are apt to belittle the contagiousness of syphilis after the fifth year.

Considering the simplicity and reliability of the dark-ground illuminator for the diagnosis of syphilitic lesions it is very strange that the method has not had a more universal application. We can explain this circumstance only by assuming that the profession has not a proper appreciation of the necessity for an early diagnosis. An early diagnosis permits us to institute a logical treatment; such a treatment should consist in the removal or destruction of the infected area at the earliest possible moment and the immediate institution of energetic mercurial medication.

In commenting on the results of excision in his experimental work, Neisser[51] says:

> These results are not very satisfying. In spite of them, however, I think now, as before, that excision should be done wherever possible. The value of excision is not affected by

these experimental results, since under all circumstances it must be useful to get rid of such an important focus of poison, as the chancre.

Hoffman says:[52]

> Since the microscopic examination now allows us to diagnose the chancre early, we must try the effect of excision or destruction of the chancre at the earliest possible time, even if the experimental work does not permit us to expect to cure the disease. Still, the removal of such a large amount of virus, perhaps, may make the disease milder, especially when combined with energetic mercurial treatment.

The list of adherents of the method of excision and early treatment of syphilis is a growing one and includes such names as Neisser, Hoffman, Hallopeau, Volk, Scherber, Rona and Lukasiewicz. All authorities are agreed on the question of antispirochetal action of mercury, but the work with the Wassermann reaction has shown us that it is necessary that the treatment of syphilis should be more energetic and more individual than has been the custom. In fact, I believe that the control of the treatment, by means of the Wassermann test—the so-called biologic treatment—is a great advance in the therapeutics of syphilis.

ABSTRACT OF DISCUSSION

Dr. G. A. DeSantos Saxe, New York City: Our knowledge of the *Spirochæta pallida* has progressed remarkably within the past two years, since Edward Spitzer, of Vienna, first showed the value of the dark-ground illuminator in recognizing this organism. There is still, however, a great deal to be learned, not only about the biologic character of the spirochete, but also about the practical aspects of the diagnosis of syphilis. Dr. Harris is very pessimistic on the subject of staining. The only method I know of that will give satisfaction in a fair proportion of cases is that of Schereschewsky, which was described in the *Centralblat für Bakteriologie*, October, 1907. This author was the first to recognize the difficulties of staining the *Spirochæta pallida*. They are twofold. First, the difficulty in spreading the smear in such a way that the erythrocytes will be sufficiently far apart to get the dye directly on the spirochetes. Second, the difficulty of avoiding precipitation in this delicate stain.

In order to obviate this, the following technic has been suggested by Schereschwesky: The clear serum from the sore, etc., obtained by means of a small curette, is spread on the slide and fixed with heat. The cubic centimeters of a 0.5 per cent. solution of pure glycerin and 13 drops of Giemsa's solution are heated in a test-tube, which must be absolutely clean. The slightest trace of acid in the tube causes a precipitate, and renders the stain useless. Contact of the slide with any grease or acid, or traces of dye cause a precipitate. The slides, therefore, should never come in contact with the fingers, but should be stained on clean glass supports. The heated stain is allowed to remain for ten minutes, and is then washed off. This method has been used in a large series of cases by White and Avery, and with it they found the spirochete in 100 per cent of chancres. I have found the method very satisfactory when all the precautions mentioned were used. I was able to find the spirochete in chancres in 100 per cent. of the untreated cases, and these results were verified by control experiments with the dark-ground illuminator. After treatment with mercury, however, the number of cases in which the spirochete was found was reduced to 50 and even 25 per cent., according to the extent of the treatment. The dark-ground illumination method takes less time and is more satisfactory than the staining method, but it is not always convenient to have the dark-ground condenser at hand.

This brings up the question: With what shall we dilute our drop of secretion in preparing it for the dark-ground illumination? I have obtained the best results by using either water or salt solution. This point may seem a trifling one, but if the results without water and with water be compared, it will be found that the spirochete is three times as distinct after using water. It swells up, becoming more refractive, brilliant and distinct. The refractive index of the serum is such that dark-ground illumination does not show the spirochete so distinctly in serum as in water. This dilution process has one disadvantage, namely, that the spirochete loses its motility more quickly, but the organism can be kept alive for a sufficient time to make a satisfactory examination. This observation has also been made by Commandon.

Sometimes, if the motions of the spirochetes are watched for some time, one can see two of them come together, join heads or tails, and wind round each other for a part of the way, and sometimes for the entire way. Sometimes one of the organisms seizes a bit of protein matter and floats about with this tiny ball, just as with a headlight. These peculiarities are, as yet, unaccounted for, and much research is needed in this field.

Dr. Howard Fox, New York: I should like an expression of opinion about the different apparatus used. For the past year I have tried both the Reichert and the Leitz dark-field illuminators. The instruments that are placed on the stage of the microscope such as the Reichert and Leitz (condenser B) are certainly much more convenient and cleanly than those inserted from beneath and that take the place of the Abbe condenser. I have used the Nernst lamp of from 50 to 60 candle power and it seems to me a perfectly satisfactory source of illumination. Does Dr. Harris for ordinary use consider the small arc light preferable to the Nernst lamp?

Dr. Maximilian Herzog, Chicago: Doctor Harris has not been the only or first one in Chicago who examined primary and secondary luetic lesions for spirochetes. I took up this work three years ago, on my return from the Philippine Islands, where I first became interested in it. I can confirm the observation of those who claim that the spirochetes are found in the great majority of cases in the primary and early secondary lesions. My first work was done before the dark-field condenser had been recommended and I had no great difficulty in finding the spirochetes in stained specimens, although it may take a great deal of time to find them in some instances, particularly in the late secondary lesions. Subsequently, I used the dark-field illuminator, but I generally found that if I could not detect the spirochetes after a prolonged search of stained specimens, I could not find them with the dark-field illuminator. I have frequently used a 50-candle power stereopticon incandescent lamp, in front of which I have a dark shield, and I employ the ordinary condenser, which is put on top of the stage. Dr. Saxe mentioned round, luminous bodies which he has found in connection with the spirochetes. These are probably due to optical effects and I would not attach much importance to the theory that the spirochete possibly feeds on these round bodies.

Dr. William S. Gottheil, New York City: I should be the last to deprecate these newer methods of diagnosis, and yet I think that we are perhaps attributing a little too much importance to them, to the exclusion of the older and established methods, very much as was the case with the surgeons and the Roentgen ray. I had occasion, a number of months ago, to see a physician with a lesion of the finger which looked very much like a chancre. I sent him, not to a tyro, but to an expert, who examined the secretion from the lesion, and the report came back, "no spirochetes." The doctor returned to me a week later and said: "I know that this is an initial lesion." A second bacteriologic examination was made, and again the report came back, "no spirochetes." One week after that he developed a pigmented papular syphilide. I mention this case only that it may serve as a note of warning against the neglect of the ordinary and customary and long-established and satisfactory methods of chancre diagnosis.

Dr. Douglass W. Montgomery, San Francisco: The assertion, I think, was made that amputation of the primary sore should be done to rid the patient of that much infection. I can not see very well how that would rid one of any considerable amount of infection. The primary sore is usually very small, no larger than a papular syphilide, and if the assertion made by Dr. Harris would hold good, it might be considered proper to excise every papule of a papular syphilide in order to get rid of so much more infection. That would be an equally logical proposition, and as a result, the patient would certainly be well tattooed. I would ask: What grounds are there for amputating the chancre with the idea of ridding the patient of that amount of infection?

---

[52] Hoffman: Deutsch. med. Wchnschr., 1905, xxxi, No. 4, p. 1712.

Dr. M.S. Heidingsfeld, Cincinnati: I concur with Dr. Gottheil that we are in danger of placing too much reliance on comparatively new tests. While the value of the laboratory tests can not be questioned, they must still be regarded in the light of aids to clinical diagnosis rather than as absolute methods. The reports that emanate from the laboratory and which receive widespread attention are apt to lead the profession into serious error. I have known the diagnosis of syphilis essayed purely on laboratory tests in cases of suspected initial lesions which at the time were clinically negative and failed to show any confirmation after months of careful observation. I do not believe that the laboratory tests in syphilis have yet reached the degree of perfected development that they overshadow the clinical features in importance. With reference to the syphilometer: I found the syphilitic regulation test of two drops to be entirely too small to convey any degree of accuracy. The manufacturers kindly supplied me with a half pound of the taurin solution and when I repeated the test, using one or two grams of clear serum in place of one or two drops, they became uniformly positive in character, irrespective of the syphilitic or non-syphilitic character of the case.

Dr. F. G. Harris, Chicago: In regard to the method of demonstrating the spirochete, to which several of the speakers referred, I worked for a long time with the staining method, with uniformly poor results. My organisms were indefinite in outline, and I was unable to identify them positively. We must have a live organism in order to make a positive diagnosis, an organism which is not deformed.

In my work, I employ the Reichert apparatus, which I prefer on account of its convenience. I use an arc light, although one may also use a Nernst lamp; with the new model of the Reichert apparatus the ordinary inverted Welsbach light may be employed.

To obtain the material, I simply irritate the chancre or mucous patch and collect the serum in a capillary tube, from which it is then blown on a clean cover glass, which is inverted on a clean slide. The specimen must be as thin as possible. If the preparation is too thick or the slide is too thick, the rays of light will not be focused at the proper point.

The characteristic movement of the spirochete in a fresh preparation is rotary, like that of an auger-bit, and that is one thing that we do not see in the stained specimen. The windings are absolutely regular in a fresh specimen, but later become somewhat irregular. In the stained specimen few of the organisms are characteristic, most of them have lost their regular windings, due to the traumatism of preparation.

As to Dr. Montgomery's question whether or not it would be proper to excise all the possible foci of infection in secondary syphilis, he misunderstood the purpose in view in amputating the original chancre. With the dark-field illumination method we are able to make the diagnosis from the very beginning of the chancre. I have found the spirochete in chancres one day old. In such cases, by amputating that focus and putting the patient on immediate treatment, we hope to abort the syphilis. Scherber, in the case referred to by Dr. Pernet, amputated the chancre and gave the patient two courses of inunctions and there were no further symptoms during the three years that he was kept under observation. By means of the dark-field illumination method we can make the diagnosis of syphilis very early, and the reasons for amputating the chancre are mainly for the purpose of preventing dissemination, just as the surgeon would remove the primary source of any other kind of infection. We remove the primary and chief focus of infection by excising the chancre, and depend on the mercury to destroy any spirochetes that are left behind. Why should we wait until the body is permeated with them?

Dr. Maximilian Herzog, Chicago: I do not think that there was any possible mistake about the character of the organism that I demonstrated in Chicago in the shape of photomicrographs. The smears had all been prepared from typical primary lesions, the cases in fact were followed up to the secondary stage. It would indeed have been strange if I should have had the misfortune to find only the *Spirochæta refringens* in typical primary lesions. Such a claim need hardly be discussed.

REGENERATION OF THE CORNEA *

MEYER WIENER, M.D.
ST. LOUIS

It has long been known that the epithelium of the cornea would regenerate itself after being destroyed intentionally or by accident.

Haller[1] as early as 1763, in his "Elementary Physiology of the Human Body," asserts that regeneration of the cornea takes place, and even the oldest ophthalmologists[2] assume that regeneration of corneal tissue occurs. In fact, Desmarres[3] states that, in experimenting on transplantation of the cornea, he has noted an increase in length of the corneal flap, and even a true regeneration. Mauchart,[4] Mead and Larry,[4] Wardrop,[4] Gulz[5], and Malgaigne[6] resected corneal scars, and found that healing took place with little or no scar. What is extremely interesting in the light of our present knowledge of the effect of an opium derivative, dionin, is the work of Muehlbauer[7] and Beger,[8] who resected the superficial layers of the cornea and succeeded in obtaining a clear cornea following the application of laudanum. Desmarres was unsuccessful in his attempt to verify these results, since the rabbits on which he operated contracted a severe purulent inflammation (infection?), resulting in heavy scars.

It is a matter of common observation that corneal wounds following cataract extractions heal so that it would be difficult to find the line of incision. Also numerous corneal opacities clear in time, where the question might easily arise as to whether there might not be a true regeneration of transparent corneal tissue in these cases.

The first systematic research for actual proof of corneal regeneration was made by F. C. Donders[4] in 1846, who suspected that it occurred, but did not think that there was sufficient proof to establish the fact. He accordingly conducted a series of experiments on twenty-two rabbit eyes, from which he resected a flap of cornea from one-third to two-thirds of its thickness, including generally about one-half of the area of the cornea or more. He examined six eyes microscopically and gives a tabulated report showing (1) the thickness of the cornea cut away, (2) the thickness of the uncut cornea, (3) the thickness of the operated part a definite period after operation, and (4) the thickness of the regenerated part in hundredths of millimeters.

He concludes that the epithelium on the injured part grows thicker than on the normal cornea; that the newly formed true corneal tissue never reaches the same thickness as that removed, but that the longer the time elapsed from the time of operation to the time of examination, the thicker it becomes; that when one-half to two-thirds of the thickness of the cornea is removed, neither inflammation nor any other abnormality occurs; and that epithelium covers the exposed surface within two days after the operation, with a gradual regeneration of cornea, slowly assuming its normal characteristics.

The only one following Donders, so far as I have been able to find, who conducted experiments on animals and made microscopic examinations of the regenerated cornea was Reich.[9] He operated on thirty-two rabbit eyes and made twenty-two microscopic examinations with results similar to those of Donders. The longest time between operation and examination was nine months. His conclusions are that the reaction and the remaining scar are so slight that the removal of thick corneal opacities by the knife are not contraindicated, but that almost always irregular astigmatism and marked light diffusion results.

Waldeyer[10] says that Sanftleven, pupil of Cohnheim, admits the possibility of regeneration of the corneal cells.

The few clinically reported cases of regeneration, all except one, followed destruction of the corneal tissues from purulent ophthalmia. Kaempf[11] reports a case of pyorrhea in a soldier in whom, after the swelling of the lids had sufficiently subsided to permit an examination of the eyeball, an apparent complete destruction of the cornea was revealed, the surface being covered with slough. Within three weeks there was a regeneration of clear cornea, except in the central part, where there was an anterior synechia in both eyes. Four months later an iridectomy performed above and outward in either eye gave useful vision.

N. D. Staicovici[12] reports a case of complete regeneration of the cornea after its destruction down to Descemet's membrane following suppurative conjunctivitis.

A case is reported from Darier's clinic[11] in a man 67 years of age who had been blind for ten years with complete destruction of the cornea with a central prolapse of the iris. The prolapsed iris underwent *an inflammation* from infection during which the entire cornea sloughed off, *leaving only Descemet's* membrane, a final regeneration of clear cornea taking place.

H. Armaignac[13] observed, in a patient suffering from a very severe acute purulent coryza, a complete destruction of the cornea with the exception of Descemet's membrane. There was an almost complete staphyloma of the cornea with a central perforation. When the patient went home there was a ring of redness surrounding the cornea two millimeters wide composed of small capillaries which had the appearance of a new growth. The patient was given a 1 per cent. solution of picric acid to instill into the eye. Armaignac was astounded when, a month later, the patient returned to him with a complete regeneration of clear cornea. True, it was traversed by very fine capillaries and sprinkled with small vague opaque spots. The anterior chamber was re-established without synechia. Unfortunately, oblique illumination revealed the pupil almost blocked by a membranous exudate. The patient could distinguish the movement of fingers at thirty centimeters. Atropin failed to break up the adhesions, but one month later vision had reached one-twentieth. The same author[14] reported a case of regeneration of the cornea after a complete destruction of the membrane following purulent ophthalmia in a woman 60 years of age.

Peter A. Callan[15] saw the cornea regenerate after its destruction from ulcus serpens. The patient, a boy 17 years of age, appeared at the New York Eye and Ear Infirmary, Oct. 6, 1903, twenty-four hours after having been struck in the eye by a rivet. There was a circular ulcer three mm. to four mm., involving all the layers, filled with a creamy white mass, umbilicated in the center. Despite cauterization and other treatment, the ulcer increased in size until on October 11 the entire cornea was involved and on October 12 the anterior chamber abolished. The next day the slough disappeared, leaving Descemet's membrane exposed. October 14 there was no more suppuration and the eye was bandaged. On October 16 cicatrization was observed over the intact Descemet's membrane. Dionin in increasing strength was given, when by March the upper half had cleared so that the pupil was visible. On June 13 vision with + 3.5 D. cyl. ax. 105 degrees was 8/70. The cornea was quite clear in the upper third, but lower two-thirds more or less hazy, resembling an eye after recovery from a severe attack of interstitial keratitis.

H. L. Wolfner[16] reported a case in which a woman 32 years of age came with gonorrheal ophthalmia of right eye. The left eye had been removed in childhood. The socket of the left eye was also infected with gonococci. When first seen there was ulceration of the right cornea, which progressed until the entire cornea down to Descemet's membrane was destroyed. Neither Wolfner nor Dr. A. Alt, who saw the case in consultation, believed that there was any hope of preserving vision. Within six weeks to two months the cornea was practically regenerated. There resulted a very thin but clear cornea, except from a faint cloud just below the center, with a slight tendency toward keratoconus and a small deposit on the anterior capsule; vision, 14/120.

In view of the partial success of the results already obtained along this line, and encouraged by the knowledge accumulated by modern studies on regeneration in general, as well as by the fact that our former investigators had no knowledge of aseptic surgery, late in July, 1908, I began a series of experiments on rabbits. From then to March 10 thirty-one rabbit eyes have been used for experimentation. Five rabbits died before notations were finished, and these have been excluded from the report. The rabbits were cocainized and wrapped in a long towel, with only their heads projecting, which served to keep them immovable. A thread was then passed through the conjunctiva and subconjunctival tissue so as to help fix the globe, which was held by the assistant who separated the lids. A flap of cornea was then dissected away varying from one-half to a little over two-thirds the thickness of the cornea, and including one-half, two-thirds, or even the entire area of the cornea, the extent of surface bared seeming to have little or no influence on the general healing process or regeneration. The only difference was that the smaller area was sooner covered by epithelium. Aside from taking general aseptic precautions at the time of the operation, no special means were taken for their after-care, the rabbits being placed in the cages without dressing or bandage. Only where occasionally there seemed to be a purulent or mucopurulent discharge after a day or two, a little powdered xeroform was dusted once daily over the cornea until the infection was controlled, which was usually within a few days. Also wherever there happened to be an unusual amount of secretion, purulent or otherwise, which might tend to agglutinate the lids, the lids were washed with warm water and the secretion removed. Following the operation the rabbits seemed to suffer no pain or inconvenience, the palpebral opening being held as wide open over the eye operated on as the sound eye, with no photophobia.

[16] Regeneration of the Cornea; report of case at Ophthalmic Section of St. Louis Medical Society, June 10, 1908.

Where only half the cornea was removed, the posterior was selected as being more readily managed on account of escaping the incidental action of the membrana nictitans. The section was commenced by making a vertical incision from above downward through the median line from the upper corneal margin to the lower corneal margin, going as deep as judgment from experience would permit without puncturing Descemet's membrane. Then from the center of this line a similar cut was made horizontally backward to the posterior limbus. The triangular was then grasped with a fine conjunctival forceps, and with slight tension, and the knife held flat, the corneal tissue was easily peeled off. Sometimes where the flap looked thin a further attempt to resect another layer was made, but this usually ended disastrously by puncturing Descemet's membrane. When this occurred an ectasia corneæ, or even staphyloma of the cornea, almost invariably took place. Twenty-four hours after the operation there was usually some slight conjunctival injection. The resected surface had a stippled appearance as though covered with a thin layer of serum or lymph, but wiping the surface with a wet sponge did not seem to change its aspect. The cut edges had a slightly raised but rounded-off look. The transparency, however, was surprisingly little disturbed. This was also the case after forty-eight hours, when the raised edges had encroached several millimeters over the raw surface. There were at this time, however, no blood vessels over the cornea except that there was an increased vascularization at the limbus.

On the third day there is generally a small milky spot about the center of the resected area, but this usually disappears within a few days, when the cornea again shows a smooth surface, being completely covered by epithelium. The resected area now shows a general infiltration or haziness which is greatest at the line of incision, but at no time to such an extent that the pupil can not be seen throught it, unless infection supervenes. This haze gradually clears until about four to six weeks after the operation a casual examination would not determine an opacity, which can only be revealed in certain positions or by oblique illumination.

In those rabbits which have been kept several months the cornea is generally apparently perfectly clear by oblique illumination as well as by transillumination, with the exception of an occasionally small, slightly hazy area.

Microscopic serial sections have been made showing the fresh cornea immediately after resection; after twenty-four hours; after forty-eight hours; four days; seven days; two weeks; one month; two months, and so on up to seven months. The specimens show a gradual thickening of the cornea the longer the period from the time of operation. Experiments are also under way on other animals than rabbits. Since, however, enough time has not been had to complete the series, I have refrained from presenting at this time the results of microscopic examination, not wishing to draw too hasty or indefinite conclusions. This is consequently offered as a preliminary report.

500 Carleton Building.

ABSTRACT OF DISCUSSION

Dr. John Green, Jr., St. Louis: Through the courtesy of Dr. Wiener I had an opportunity of examining the animals operated on by him. The line of incision was represented by a very delicate linear scar and the area corresponding to the exsected portion was faintly nebulous. The nebula was visible only by oblique illumination. The contour of the cornea in the exsected portion seemed to be about the same as in the unoperated part. In future experiments it would be well to observe the reflections of the cornea from Placedo's disc before operation and for some months afterward, to determine, if possible, how much distortion of the corneal surface had occurred, and whether regular or irregular astigmatism had developed. Two facts have been brought out which indicate that a true regeneration has taken place: First, the absence of any notable opacity shows that a very small amount, if any, of scar tissue has formed; second, the evenness of the corneal surface, there being no irregularities of the epithelium.

Dr. William Zentmayer, Philadelphia: Recently in a case of nodular keratitis I dissected out a nodule down to the membrane of Descemet and I can say that after a few weeks the corneal tissue apparently had been regenerated, as the resulting space was filled in almost to the level of the surrounding corneal level. I did not examine it with the loup, but with the naked eye it appeared transparent.

Dr. R. L. Randolph, Baltimore: I have been very much interested in these observations of Dr. Wiener, and have been long impressed with the reparative activity in the rabbit's eye particularly and in the eyes of the lower animals generally. Some years ago in some experimental work in the reproduction of the crystalline lens I succeeded in getting as many as three lenses from an eye in the course of a year. Whether this reproductivity finds any analogy in human beings is doubtful, but I cannot help thinking that what we call secondary cataract is perhaps an effort on the part of Nature to form a new lens. We know that the lens in the lower animals is formed by the reproduction of the cells on the anterior capsule by the growth of these cells into spindle cells and subsequently into lens fibers, and we have pretty much the same process in human beings. As regards the rabbit, I have been astonished at the quickness with which superficial abrasions of the cornea get well. A fine scratch across the cornea in the case of the rabbit will disappear absolutely in two or three hours, where it is perfectly possible in the human being still to reveal it late in the day with the aid of fluorescin. This is very surprising in view of the fact that the bacterial flora of the conjunctiva in the rabbit is practically identical with that of the human being; in other words, its cornea has much the same conditions to contend with as has the human. What this is due to I have never been able to say. It is suggested that the leucocytes in the rabbit's cornea are exceedingly active. I am a little skeptical as to the repair of so serious a wound in the human as Dr. Wiener has spoken of.

DR. A. R. BAKER, Cleveland: No doubt all of us have seen cases of ophthalmia neonatorum in which there is an anterior polar cataract and doubtless there must have been a perforation of the cornea; and yet we have seen those persons later in life when little or no opacity of the cornea existed. I have seen several cases with 20/20 vision after the lens has been removed, so that it seems probable there may be a regeneration of the cornea in young persons. I do not think that I have ever seen this occur in adults, although we have all seen cases in which the epithelium has been entirely restored. Only recently in the case of a burn from an explosion of chemicals the corneæ of both eyes were entirely opaque. The physician in attendance gave a verdict of total blindness, yet in a few hours the entire epithelium peeled off and in the course of a few weeks the patient recovered perfect vision. We have all seen these cases. I must confess, however, that I am pessimistic as to the permanent result of regeneration of the deeper portions of the cornea. Many years ago I made experiments on guinea-pigs similar to those of the essayist; results were favorable at first, but disappointing later. Transplantation of the cornea has been one of the dreams of the oculist for hundreds of years. The primary results are always flattering, but the ultimate ones are disappointing.

DR. R. F. MILLER, St. Louis: Through the courtesy of Dr. Wiener I had an opportunity to see the animals he operated on, and I would like to say that many of these cases showed very beautiful results. I also happened to be present when he operated on the human, and I must say that from all appearances the outlook is certainly beautiful, and, as the doctor reported, about three days afterward the condition seemed to be about the same as in the animals. So I think the doctor has opened up a subject again which has been tried many times, but perhaps with careful detailed work he will be able to accomplish a great deal more than was accomplished twenty-five years ago. The work was very interesting to me and I think with future trials will give very good results.

DR. M. WIENER, St. Louis: In regard to the corneal reflections in these photographs which I pass around, there is one rabbit which shows the regular reflection of the window in the eye, while the other eye shows an irregular reflection of the window. In one eye we got a clear cornea after resection and in the other we got a fairly clear cornea. The reason we got the clear cornea is that I believe the cornea was dissected out as it should be, that is, in layers. The piece should not be taken out irregularly in ridges, but evenly, and it can easily be done, almost peeled off in separate layers. I think this is essential in order to get a clear and regular surface. So far as having a regeneration, one microscopic specimen surely shows thickening of the cornea in the late specimens from that of the earlier ones; also, immediately after the operation, microscopically we can see a distinct depression, which later smooths out perfectly. Dr. Randolph believed it could not be done in cases in which there had been serious inflammation. These experiments were done on account of my having read of and seen a case of regeneration of the cornea after a gonorrheal ophthalmia, and that is certainly a severe process of inflammation. If the cornea can regenerate after a gonorrheal ophthalmia we ought to be able to take a clean scar and resect it. Dr. Baker thought it would be feasible, perhaps, only in the young. I have taken old animals as well as young, and the regeneration of the cornea mentioned in this paper was in an adult. I mentioned in the paper that after the operation these animals were put in the cages and nothing done with them at all. Their eyes were left open. If there was an unusual amount of secretion it was wiped off from day to day and possibly a little antiseptic powder used. Now I have started a series of experiments to determine whether there is any more rapid regeneration or clearing in eyes not treated as compared with eyes treated with dionin.

Knowledge of Drugs.—"Learn how to prescribe remedies and you will complain less of their inefficacy and their dangers."—Cappiovaccio of Cremona in the sixteenth century.

THE OPERATIVE TREATMENT OF GLAUCOMA BY CYCLODIALYSIS *

ARNOLD KNAPP, M.D.
NEW YORK

The operation of cyclodialysis suggested by Heine in 1905, consists in making an artificial communication between the anterior chamber and the suprachorioidal space, allowing a new channel for the escape of the aqueous humor and thus reducing intraocular tension. The operation is performed under local anesthesia by making an incision in the sclera 6 to 8 mm. posterior to the sclerocorneal junction after reflecting a conjunctival flap and with a bent spatula, separating the ciliary body from the overlying sclera and breaking through the pectinate ligament. A quadrant of the iris periphery is then detached. I have performed this operation in eighteen cases specially selected to test its merits. These cases have now been observed for a sufficiently long time to permit an opinion on the value of this operation.

The cases can be arranged in the following groups:

A. CHRONIC GLAUCOMA

These are cases in which an iridectomy did not succeed in permanently reducing the tension, or a contraindication to an iridectomy was present.

CASE 1.—R. B. M. Age 55. L. Vision=20/20—. T. (Tension)+1. Fn. (Field normal) Nov. 14, 1905; Iridectomy. T. again increased after six weeks. June 2, 1906: Cyclodialysis. At operation some difficulty in breaking through pectinate ligament. Aug. 1, 1906: Tn. V.=20/30. Dec. 1, 1906: Some opacities in posterior cortex of lens. Tn. (Tension normal) March 22, 1909: T. has remained normal without any miotics; cataract nearly mature.

CASE 2.—E. M. R. Age 60. Aug. 1, 1905: Iridectomy. Notwithstanding drops, eye showed tendency to be hard. V. = 20/30. F. contracted nasally and below. May 21, 1906: Cyclodialysis. During operation anterior chamber filled with blood. This was evacuated by paracentesis two days later. V.=20/40. On the last visit, May 6, 1908, V.=20/30; F. no change. Tn. Has occasionally used miotics.

CASES 3 AND 4.—S. G. Age 45. R. absolute glaucoma. L. 20/100. T.+. F. contracted nasally to 10 degrees. March 20, 1906: R. cyclodialysis. April 1, 1906: No reaction. No chorioidal detachment appreciable. Tn. April 4, 1906: L. cyclodialysis. April 20, 1906: R. T.+; L. Tn. March 10, 1907: R. T.+. L. 20/70. F. no change. T+½. To use drops. April 3, 1908: L. tension kept slightly elevated, hence cyclodialysis repeated in left eye. F. nasally contracted to 5 degrees. Incision in sclera external to old one. On introducing spatula instrument passed into anterior chamber without encountering any resistance. June 17, 1908: L. Tn. 20/70. R. T.+. Dec. 30, 1908: L. Tn. Feb. 24, 1909: L. Tn. R. T.+.

CASE 5.—M. W. Age 56. Marked arteriosclerosis. R. widely dilated pupil. T.+. Od. cup with atrophy. V.=20/100. F. nasal contraction to 5 degrees. May 2, 1907: Cyclodialysis. Uneventful. June 17, 1908: R. 20/200. Tn. No miotics. March 2, 1909: Tn. V.=20/200. No drops.

CASE 6.—P. P. Age 61. R. iridectomy, 1905. May 1, 1907: R. V.=20/200. F. 15 degrees nasal. 30 degrees temp. T.+ Cyclodialysis. Uneventful, June 10, 1908: R. 20/200—; T.+?. F. Slightly more contracted. March 8, 1909: T.+.

CASE 7.—A. G. Age 42. R. 20/200. F. 80 degrees temp. 35 degrees sup. 35 degrees inf. 30 degrees nasal. T.+. Aug. 27, 1908: Cyclodialysis. During operation anterior chamber filled with blood. That evening attack acute glaucoma, re-

lieved by hot applications, eserin (physostigmin) and dionin. Nov. 28, 1908: T.+. Arc of iris detached showed atrophy of stroma. Feb. 24, 1909: T.+.

Cases 8 and 9.—J. S. (R. and L.) cup with atrophy. July 31, 1908: R. cyclodialysis. Aug. 7, 1908: L. cyclodialysis; both uneventful. Aug. 20, 1908: T.— in both. R. V.=m. h. (movements of hands) L. V.=20/70. F. 25 degrees nasal. 30 degrees sup. 10 degrees inf. 45 degrees, temp. September 9, 1908: Tn. each Oct. 12, 1908, last visit, Tn. each.

Case 10.—F. W. Age 40. L. od. cup with atrophy. V.= hand movements in temporal field. T.+ Sept. 29, 1908: Cyclodialysis. Some hemorrhage and posterior adhesions. Oct. 13, 1908: T.—. Small hemorrhage on disc. November 27, Tn. F. had enlarged. March 29, 1909: L. opac. vitr. T.—. V. no change. F. enlarged.

Case 11.—R. F. Age 50. L. iridectomy two years ago. Deep cup with atrophy. V.=20/100. F. contracted to small temporal area. T.+. June 27, 1908: Cyclodialysis. Uneventful. Feb. 20, 1909: V. 20/70. Tn. Field enlarged.

Case 12.—T. C. A. Age 60. Feb. 27, 1907: L. V.=10/200. F. contracted to temporal half. T.+. Nov. 27, 1907: Cyclodialysis. Uneventful. T. reduced. Optical iridectomy later for old opacity of cornea. April 4, 1908, last visit, 10/200. Tn.

Case 13.—A. S. Age 62. Chronic glaucoma with atrophy. L. 20/70—. T.+. Dec. 2, 1908: Cyclodialysis. Very difficult to enter anterior chamber. Jan. 26, 1909: Last visit. L. 20/100. Field enlarged out and down. Tn. (no miotics).

Cases 14 and 15.—M. L. Age 26. V. always poor, especially for last six months. R. 20/200. T.+. F. irregular contraction. L. m. h. T.+. F. contracted to temporal and superior quadrant. Very deep cup. Pronounced atrophy. Dec. 18, 1907: R. cyclodialysis. T. reduced and remained minus. Dec. 26, 1907: L. cyclodialysis. After 1 week, T. rose again. Jan. 6, 1908: Repeated operation. T.— since. Jan. 20, 1908: R. 20/200. L. 20/200. Fields enlarged. Aug. 28, 1908: R. T.+ again. L. T.+. R. cyclodialysis repeated. Favorable except that it was followed by retinal hemorrhage in macula. Sudden attack acute glaucoma requiring paracentesis. Jan. 7, 1909: R. cyclodialysis repeated. Down and out. T. very soft. Cornea slightly collapsed. V. eccentric 3/200. L. T.— V.= 20/200. F. enlarged.

B. CONGENITAL GLAUCOMA

Case 16.—J. G. Age 1 year. Parents first cousins. At six months diagnosis made. July 1, 1908: Deep cup. Prescribed pilocarpin. Eyes enlarged. Corneæ dull. Cyclodialysis in both. Sclera very thin. No resistance whatever at ligament. Aug. 1, 1908: R. again hard. L. Tn. Mother thought that child could now see. Dec. 30, 1908: Tn. each. Jan. 6, 1909: R. Tn. L. T+. Using pilocarpin 2 per cent.

C. EXTENSIVE CAPSULAR ADHESION TO CORNEA

Case 17.—A. C. Age 30. Dec. 2, 1907: Struck in eye with stick. Transverse wound of cornea. Irideremia. Broad adhesion of lens capsule to corneal scar. T. remained hard notwithstanding all medicinal treatment. Jan. 20, 1908: Cyclodialysis. On passing spatula an obstruction encountered more posterior than usual. A quadrant detached. T. not perceptibly reduced. On following day eye very hard. This continued; tension somewhat reduced by daily pilocarpin sweats. Jan. 26, 1908: T.+. June 3, 1909. Glaucoma absolute and degenerate eye.

D. GLAUCOMA SECONDARY TO NEURORETINITIS WITH VASCULAR CHANGES AND RETINAL HEMORRHAGES

Case 18.—S. Age 46. Acute glaucoma not controlled by miotics, sweats, and mercurial injections. Cyclodialysis. T. reduced for two days, then relapse. Patient lost sight of.

In brief the operation has failed in congenital glaucoma (Case 16), in glaucoma secondary to extensive capsular adhesion to the cornea (Case 17), and in glaucoma secondary to neuroretinitis with endarteritis and hemorrhages (Case 18). It has been partly successful in cases of chronic glaucoma (Cases 1 to 15) as will be seen in the following summary:

Case 1.—T. remained normal without miotics to present date, a period of two years, nine months.

Case 2.—T. remained normal with occasional use of miotics to date of last visit, two years.

Case 3.—T. remained normal for one year then became hard.

Case 4.—T. remained down for one year and a half, then operation repeated and T. has remained down to present date, eleven months.

Case 5.—T. has remained down to date, one year, ten months. No miotics.

Case 6.—T. remained down for one year, has now been somewhat raised for ten months, incompletely controlled by miotics.

Case 7.—T. reduced for four months. Has now been elevated for three months.

Cases 8 and 9.—T. down at last visit, two months, without drops.

Case 10.—T. down now for six months since operation.

Case 11.—T. down now for nine months.

Case 12.—T. down during five months' period of observation.

Case 13.—T. down at last visit, two months.

Case 14.—T. down for one year, eight months, with enlargement of field; operation repeated then (August, 1908), followed by hemorrhage in macular region, attacks of acute glaucoma; operation repeated in January, 1909. T.— since. V. very much reduced as field is eccentric.

Case 15.—T. down for one week. Operation repeated. T.— since; period of observation one year, three months. V. and F. improved.

These were all cases selected to test the value of cyclodialysis, in which an iridectomy had been performed with no permanent benefit or in which, on account of the advanced stage of the glaucoma, the atrophy of the optic nerve, the restricted field or the condition of the iris, not much result could be expected from an iridectomy. Of these the tension was reduced in eleven for observation-periods varying from two years and nine months to two months. In the remaining four the tension again became hard.

The operation is technically easy, much easier than a correct iridectomy. The difficulties encountered in breaking through the pectinate ligament differed and were readily recognized. In one in which at the second operation the same quadrant of iris was displaced, no resistance at all was felt as if a firm adhesion had not reformed. In one case this segment of iris subsequently developed distinct atrophy of the iris stroma. In one of the most favorable cases a cataract developed, the opacity beginning in the posterior cortex. It is impossible to say whether the cyclodialysis was responsible for this. The operation did not aggravate the condition except for a macular hemorrhage in one, and attacks of acute glaucoma in two. No vitreous disturbance or detachment of the chorioid were observed. The operation was repeated with benefit in three cases. In one (Case 14), the eye subsequently exhibited marked hypotony which apparently was not harmful but this again is a point requiring further observation. Why the operation succeeded in some, and in apparently similar cases the tension again rose, can not be explained.

It can be conservatively stated that cyclodialysis is of value in certain limited conditions; it is indicated in the advanced cases of chronic glaucoma, especially those in which iridectomy has not succeeded in reducing the tension. It can not in any way replace the classical operation of iridectomy or its recent modifications in incipient cases of chronic glaucoma.

26 West Fortieth Street.

ABSTRACT OF DISCUSSION

DR. E. V. L. BROWN, Chicago: My experience with cyclodialysis extends over a period of but 16 months and has been confined to twelve operations on nine glaucomatous eyes, in which iridectomy could not be done or was inadvisable. A tabulation[*] of the data available at this time covers the following points: Name, address, age, type of glaucoma, cause of the glaucoma, duration of the preceding eye disease, probable duration of the increased tension, previous operations for glaucoma, reason why iridectomy was not done, date of cyclodialysis, eye operated on, site of scleral incision, extent of the separation of the root of the iris from the sclera, complications at the time of the operation, tension before operation, immediately after and three days after operation, as well as when the patient was last seen, any other cyclodialysis or iridectomy operation necessary, vision before and after operation, depth of the anterior chamber and dimensions of pupil, respectively before and after operation, subsequent elevation of tension, period of observation in which tension has remained normal, and a notation as to whether or not I consider the particular operation a success or a failure at this time.

The data may be summarized as follows: the operation was successful in five cases, 1, 2, 4, 5, 8 (55 per cent.) and was unsuccessful in four cases, 3, 6, 7, 9 (45 per cent.). In two of the successful cases (1 and 2) the patients required a second cyclodialysis to reduce the tension permanently, and a third eye (Case 3) had to be enucleated because increased tension and pain persisted after two cyclodialyses; in a fourth (Case 9) increased tension returned, and was permanently relieved first by iridectomy.

All the successful results were in secondary glaucoma cases; three were chronic glaucoma, two secondary to adherent leucoma (Cases 2 and 5), and one secondary to anterior iris root synechia (Case 1), and one was subacute and secondary to adherent leucoma (Case 8), and one was an acute case secondary to traumatic dislocation of the lens into the vitreous (Case 4). The increased tensions before operation were respectively +1, +1, +2, +1, +¾; average, +1. The probable duration of the preceding eye disease in these five cases was respectively, 9, 5¾, 2, 6, and ¾ months; average, 4¾ months. The probable duration of the increased tension was respectively about 1, 4, 4, 2½ and 1 week; average, 2 weeks. The subsequent period of freedom from glaucomatous tension has now been respectively over 13, 1½, 14, 11 and 12 months, or an average of ten months of normal tension.

The vision in the three chronic cases was and has remained *nil*; in the subacute case it improved from the counting of fingers at 3 meters to 20/30 with correction; in the acute case it improved from *nil* to 20/200. The depth of the anterior chamber was improved in only the two cases of adherent leucoma.

The four unsuccessful cases were all chronic, one of them secondary (to plastic iritis, Case 3) and three of them were of the primary type of the disease (Cases 6, 7, 9). The tensions before operation were +2, +2, +1, +1; average, +1½; the probable duration, 5, 9, 18 and 0 months; average, 6½ months. In the secondary glaucoma case another cyclodialysis was of no avail, and as no iridectomy could be performed the eye was enucleated. In one of the three primary cases (Case 9), the anterior chamber was so deepened that a successful iridectomy could be performed, and in the remaining two patients (Cases 6 and 7), there has been entire freedom from inflammation, tenderness and pain for 11 months in each case, although the tension is now +2 in each. I do not, therefore, consider these last two cases unqualified failures, although I have listed them among the failures; on the other hand, a second cyclodialysis may permanently relieve the increased tension in these cases, as it did in Cases 1 and 2. The patients have each consented to a second cyclodialysis.

From my own cases, I am therefore in favor of giving cyclodialysis a further thorough, and if necessary, repeated trial in glaucoma, at least in eyes blinded by chronic increased tension, and especially that form caused by and secondary to anterior synechia and adherent leucoma, in which an iridectomy can not be performed or is inadvisable.

DR. H. GIFFORD, Omaha: This operation is an excellent example of one which was conceived on a wrong principle, but has turned out to do pretty good work. I think if you expect it to produce a permanent opening from the anterior chamber into the suprachoroidal space you are going to be disappointed. The results of the microscopic examination do not bear out any such theory, and on general principles it is absurd to expect it. What this operation does do is to cause a certain atrophy of the ciliary processes, which are factors in producing the hypertension. I think it is important to recognize that this is the way it reduces the tension, because if a second operation is to be done it ought not to be done in the same place, but in a different one, so as to produce as much atrophy of the ciliary processes as is safe. Some will remember a series of experiments by Deutschmann many years ago in which he excised the ciliary processes without serious reaction and without interfering with the general macroscopic appearance of the eye, except by reducing the tension very materially. That, I think, is an explanation of the results of this operation. I might say a similar explanation has been suggested by Krauss of Breslau.

DR. W. H. WILDER, Chicago: I am not prepared to draw any definite conclusions from the limited experience I have had with this measure, but I have tried it in four cases, in one of which the result was most surprising and gratifying. It was a case of acute glaucoma with tension plus 2, vision 20/100, steamy cornea, contracted fields, especially at the nasal side and shallow anterior chamber. On preparing to do an iridectomy, the chamber seemed so extremely shallow that I decided to do a cyclodialysis, as a preliminary to a later iridectomy. The operation was done with cocain anesthesia, and without difficulty. The following day the tension was normal and the pupil became smaller. In a few days the central vision began to improve, and at the end of two weeks I was pleased to note that the patient had 20/30 of vision, and that the fields had improved to about the normal limits. This fortunate condition remained for a period of four or five months, during which time I was studying the case, and then the man passed from my observation.

The operation might be performed as a substitute for anterior or posterior sclerotomy in those cases of acute glaucoma in which one wishes to lower the tension before attempting the more difficult iridectomy. If it is possible, as claimed by some observers, to reduce the tension gradually by proper and careful manipulation of the instrument with which the ligamentum pectinatum is detached, I can see now the operation might be valuable in cases of hemorrhagic glaucoma or in patients with extremely high tension in whom we fear hemorrhage or some serious accident in doing an iridectomy, or even a sclerotomy. In the other cases I had the results were doubtful, to say the least. In one it was repeated three times without good effect, but even a later iridectomy failed to relieve the condition.

Reinfection with Syphilis.—F. John has compiled 356 cases of reinfection with syphilis as recorded in international literature. The list includes 34 in which the first infection was inherited. His work is published as Nos. 525 of the *Sammlung klinischer Vorträge*, just issued, and forms a volume of 248 pages. The various cases are grouped in tables according to the manifestations of the second infection, and the opinions of 66 well-known clinicians are appended, some accepting the possibility of reinfection and the others doubting it. Neisser's experience with monkeys has converted him to the former view. John's conclusions from this material are that the evidence as to reinfection is not very conclusive to date, but that it seems probable that the acquired immunity is not absolute and becomes attenuated in time. Reinfection is no proof of the curability of the disease as it can occur with existing tertiary lesions. Reinfection is observed almost exclusively among the well-to-do. On the whole, he adds in conclusion, the majority of cases of reinfection on record are apocryphal.

---

[*] Because of lack of space this table is omitted from THE JOURNAL, but it appears in the Transactions of the Section. A copy of the table will be sent to any one requesting it within four weeks and enclosing a stamped addressed envelope.

DOUGLAS C. MORIARTA, M.D.
SARATOGA SPRINGS, N. Y.

My subject is of great importance to every practitioner of medicine, as there is none of us who does not have occasion at some time either to give an anesthetic or have one given. Any untoward result from the anesthetic affects the reputation of the operator; it matters not whether he is an isolated practitioner or a busy operator in one of our large clinics; for even if one expert in the administration of an anesthetic be in charge of the case the patient still looks to his surgeon for his safety and expects him to guard it.

You will agree with me that posing as a critic is not a pleasant position to assume, neither is it apt to be a popular one. Yet "fools rush in where angels fear to tread," and I shall venture to present my opinions in this very important field of our professional work. I feel sure it is the one field in the practice of medicine in which there is seemingly indifference and lack of proper comprehension.

At the beginning, I might say, I have reached the conclusion of many others, i. e., the danger of anesthesia is largely due to the anesthetist. I do not mean by this that there are not pathologic conditions necessitating a particular anesthetic which, when administered, may result disastrously for the patient, and the result be due entirely to the drug. But I do say that I believe it is safer for the average patient to have one of the more dangerous anesthetics, chloroform, for instance, administered by one competent to give it, than it is to have ether, the safest of all anesthetics, given by an indifferent practitioner. And by "indifferent practitioner" I mean a person who is careless in observing the physiologic action of the drug, or the pathologic condition produced by it; this, either through ignorance or because the anesthetist becomes interested in the operative procedures, or allows his attention to be distracted by those present, either nurses or visitors. Morally, I believe that we are occasionally responsible for a fatal anesthesia, and technically such a result approaches malpractice (and that we have not been called on to defend our acts in these cases, in civil procedures, is fortunate). That this is so is, to my mind, a stigma against our profession; for why should not a patient have as much right to expect and exact skill in this branch of medicine as in the treatment of a fracture, in a pneumonia or typhoid fever? And if a civil action were brought to recover alleged damages, and your attorney attempted to prove you qualified as a competent anesthetist at the trial, how much teaching or clinical instruction could you certify as having had? About all that the average practitioner could say, if called on to show himself qualified, would be that he was a regularly graduated physician and surgeon, and supposed to know and be familiar with anesthetics, their administration and resulting anesthesia. And, I ask, what percentage of us have received clinical training or instruction in the administration of anesthetics? The number is so small that it is a disgrace to our colleges. And the general teaching has not materially improved. Even at this present writing there are only a few of our colleges where this most important branch of our curriculum is taught clinically; and, to repeat, is it not a disgrace to those in which it is not? And, if the actual state of affairs were appreciated by the public, even by the board of regents, would not a reform be demanded in this particular?

Those of us who were not taught the proper administration of anesthetics while at school, and who realize our lack of education and skill and seek to inform ourselves in the art, must visit for this purpose the leading clinics of the country; for at what other place or institution can the knowledge be acquired? But the one who does so visit these clinics will do well if he is not deceived by the procedures of the anesthetists, who may there be witnessed doing their routine work. For I unhesitatingly state that during the past few years I have seen some of the most atrocious examples of this work in the clinics of surgeons of national and even international reputation that I have ever observed anywhere. I mention with much pleasure, however, two clinics where the technic in anesthesia seems ideal; I refer to the clinics of the Mayos of Rochester, and Crile of Cleveland.

The amount of information to be acquired in this art by a visit to either place, if you are accorded the privilege of observing their methods, is marvelous and well worth the time of any practitioner. If one has not the opportunity for such observation at these places, then some other instructive clinic should be substituted, or this particular work should be refused until the proposed anesthetist has properly prepared himself.

I purpose discussing the anesthetist only on the clinical side, and I state without fear of contradiction that those of us who are doing this line of work—I speak, of course, of the profession as a whole and do not include the few who have become proficient in the art—do not seem to realize or appreciate the responsibility or dangers, or our lack of the qualifications necessary, in order skilfully to perform the work we are undertaking. For surely, if we stop to think, we must know that the life, as well as the immediate comfort of the patient, is in our hands. In making these statements, I do not have in mind the desperate cases, which tax the skill of the trained anesthetist; nor yet the skill needful to determine the particular anesthetic indicated in some few pathologic conditions; or the method to be employed in particular cases. But I refer to the ordinary physician, administering an anesthetic as he is wont to do in his routine work, when the patient is considered to be in a safe condition to endure such procedures as are anticipated by the operator. Thus I believe the proper amount of care is not generally exercised in administering anesthetics, and I am constrained to say so, because my deductions are drawn from many observations, including my own work.

I may justly be criticized, and the question may be asked why I do not improve my methods, if I am convinced, as I have stated, of existing defects. My reply would be that it is easier to ask the question than to answer it with the proper justification. I admit that the fact that a patient can not pay for the skill of a trained anesthetist is no justification; neither is the fact that precedent directs that an interne must acquire the knowledge incident to the proper administration of anesthetics, as a matter of convenience, a justification; or that some associate is willing to serve in this capacity, although deficient in experience. And I might further emphasize the situation by saying that if we accept work necessitating an anesthetic, and serious complications follow its administration, there is no justification for us, unless a competent anesthetist was administering the anesthetic. For it goes without saying that all pa-

---

* Read before the Saratoga County Medical Society, Feb. 14, 1909.

tients are entitled to, and should be given, the safest possible care when they place their lives in our hands, and how they may have it is the problem always confronting us. I am growing more and more to believe that only a few are adapted to this work; some will never be safe when serving in this capacity, regardless of opportunity or experience. Perhaps, like those in other special lines, anesthetists are "born, not made."

But to whom are we to trust our patients requiring an anesthetist, and what should be the qualifications of the one whom we shall select for this duty? The first part of this query seems easy to answer, and one might say, "Employ only a competent person." But how is the general practitioner, the occasional operator, or the small hospital always to secure a competent anesthetist? The only reply is that we should acknowledge our defects, if they exist as I have stated, and proceed to correct them by raising the standard of the whole profession in this art.

In opposition to this statement, it might be urged that the task, when the entire profession is considered, is too great, and it can never be accomplished. On the contrary, in my judgment, as soon as the necessity is appreciated by the profession at large, it will be met, as well and as easily as was the acquiring of aseptic methods in our surgical work five years ago, at which time it was shown that the safety of our patients demanded it.

The second part of the query is not difficult to answer, because a safe and proper technic is known; and it only remains for us to inform ourselves in regard to its details. Surely an anesthetist should be thoroughly familiar with, and trained in, the administering of the drug; he should know its action and peculiarities in different instances, and thus be able to recognize the earliest danger symptoms, and know how to meet them.

Watchfulness will prove a valuable prophylactic measure. The successful anesthetist will be an individual of keen perceptions, of good judgment, of a pleasing personality, and one capable of securing the confidence of the patient, and of controlling and arranging all details incident to the anesthesia, from the time he commences the anesthetic until the surgeon has finished.

Finally, an accurate knowledge of the relative sensitiveness of regional fields is imperative. No person who dislikes administering an anesthetic, or who has an irritable temperament, or gruff manners, and can not appear to be interested in the patient's welfare, or one who is habitually in a hurry or can not give his entire thought to the anesthesia, should ever be allowed or attempt to give one.

In every case in which an anesthetic is administered, there are certain imperative cardinal principles which should be scrupulously observed.

The anesthetist should never be in a hurry, as his apparent haste is apt to alarm the patient, while a few moments spent with the latter in quiet conversation is of the greatest benefit and invariably a time-saver. He should examine and determine for himself the condition of the lungs and heart, and if not previously informed should learn the condition of the urinary secretions. At this time he can also ascertain if there are any loose teeth in the mouth and determine if the patient is properly clothed. He should also explain that the sensation of choking produced by the anesthetic is a common one and is not attended with danger; and that if at this time the patient can control himself he will drop off to sleep quietly and easily.

Before commencing the anesthetic, emergency remedies should be at hand and ready for use. The time at which he should begin the anesthetic should be planned with the operator, so that the patient will not have to wait for the operator, as it is decidedly better and safer practice for the operator to wait for the patient.

The anesthetic to be used should be determined by the anesthetist and operator, and the method should be the one with which the individual is most familiar, and by which he can safely and easily produce the lightest anesthesia under which the operator may proceed. He should be in touch with the operator in the steps of the procedure that the sleep may be as light as possible and yet the operator not be delayed by too slight an anesthesia. A profound anesthesia is always dangerous and should be avoided if possible.

Once the anesthetist has begun, all unusual noise, bustle or excitement should cease. I do not mean that the usual preparations should not proceed, but they should be carried on in an orderly and methodical manner, that there may be no unusual noise to disturb the patient.

I am sure that there is a positive psychical advantage in the anesthetist's keeping up a conversation and talking to the patient from the time he starts the anesthetic; it reassures patients and quiets them and they will drop off to sleep more easily. Under no condition should he ever direct the patient to take a full long breath; and from the time the patient goes to sleep until the operation is finished he should be on the alert to the patient's condition, carefully watching the vital forces, as well as observing the earliest manifestations of approaching danger. I believe that the anesthetist should remain with the patient until he is safely in bed and in the hands of some one competent to determine postoperative complications.

In conclusion, I believe that the Anesthesia Commission of the American Medical Association should formulate specific directions for the guidance of the general practitioner, which should be an exact and concise description of the one best method to be generally followed, and this should represent the consensus of opinion. In making this statement, I am not unmindful of the value of the information contained in the report of this commission at Chicago in 1908, in which has been fully outlined the advantages of and contraindications against each of the several anesthetics, as well as the various devices employed in its administration. But I believe and know that the isolated general practitioner would very much appreciate and be greatly benefited by a direct expression concerning one method which he could adopt and feel secure that he was backed by such an authority. The directions should be concise, and yet in sufficient detail; possibly the advantages of such uniform procedure might extend to others who believe themselves competent. It would then only be necessary for the practitioner to differentiate in exceptional cases.

Resistance.—Dr. S. Flexner gives in his university lecture on "Public Health" at Columbia University (*Popular Science Monthly*, July, 1909) a clear exposition for intelligent laymen of the resources of the body for the resistance of disease and the artificial means of increasing them, developed by modern biologic research. The fact is clearly brought out that so far serum treatment has been successful chiefly in a prophylactic way because, when used with the disease well established, the destruction of a large number of bacteria is liable to set free an amount of poison with which the organism in unable to cope. This fact clearly appreciated by laymen, should give an added reason for attention to the public health.

THE ROENTGEN RAYS IN DENTISTRY*

G. E. PFAHLER, M.D.
PHILADELPHIA

That the Roentgen rays are useful in dentistry needs no argument before this Section, and that they should be more generally used I believe will be affirmed by all who have had experience with them. Most of the patients who are finally sent to the roentgenologist for examination have usually suffered months and even years with conditions that only needed a Roentgen examination to make the diagnosis clear and the line of treatment definite. As a matter of fact, most of the patients that come to me are those who have finally reached the consultant, who recognized the importance of an examination. Some of these patients had been tampered with for months or years by general practitioners of medicine or dentistry, and often teeth have been unnecessarily sacrificed. Surely the dentist with the greatest experience needs this exact method of diagnosis least; and yet, I repeat, nearly all my patients come from the consulting dental surgeon.

There is scarcely a case in dentistry in which some definite information can not be obtained, but it would be absurd to say that every patient should be examined with the Roentgen rays. It is, however, only fair to patients that every chronic or obscure case should have the benefit of this method of exact diagnosis. The skill of the modern dentist is simply marvelous and it is the most expert who welcome aid in diagnosis.

OBJECTIONS TO AN X-RAY EXAMINATION

To-day there can be no real objection to an x-ray examination. It is clean, aseptic, painless, and absolutely without danger in the hands of an expert. The reason for discussing this subject is the morbid fear that has often been aroused in the minds of patients by stories published in lay journals. Most of these stories have been true, but the facts have been misinterpreted and misapplied. That the rays have done damage no one can deny, but practically all damaging results occurred in the early days of roentgenography or in the hands of incompetent men.

During the past nine years in which I have been specially interested in dental roentgenography I have never had a harmful result following one of these examinations. To-day they are made with a few seconds' exposure, usually not over five, and never over thirty seconds. Any danger present to-day comes to the operator, who should do no work until he has learned to protect himself.

The fluoroscope has no place in dentistry. It is clumsy, inaccurate and dangerous to both the patient and operator. Lange[1] says:

> To the indiscriminate use of the fluoroscope many of the early errors in x-ray work can be directly traced. The image on the screen bears no comparison to the fine detail and distinctness which is obtained in the photographic plate or film.

A FEW HINTS IN TECHNIC

The rays should be confined to the area examined. They should be directed accurately to the point of greatest interest. This can be accomplished by means of the localizer which I described two years ago[2] before this Section. The same result can be fairly well accomplished when small cylinders are used. Secondary rays should be eliminated by means of diaphragms and cylinders.

When the disease or symptoms are confined to a few teeth or roots, and especially when affecting the upper jaw, the best results are obtained by placing a small film in the mouth. In this way the film is brought into almost direct contact with the teeth and the alveolar process, and the most beautiful detail is obtained. If, however, the bone, the accessory sinuses or large dental areas are to be studied, the roentgenograph is best obtained by the use of a plate placed outside of the mouth or face. Before this Section two years ago I described the technic by which every part of both the upper and the lower jaws could be clearly shown on the plate. Generally speaking, one should expect only two or three teeth clearly shown on either film or plate, and on this account the dentist should designate as nearly as possible the area to be examined.

The use of the plate is absolutely necessary in the study of the bone or the accessory sinuses, but it is also very desirable in searching for missing or unerupted teeth, in which instance a small film might not include the missing tooth and might thus lead to an error. Generally I use both film and plate and thus make one confirm or rectify the other.

The roentgenograph or x-ray picture is an accurate photographic record of the variations in density of the tissues traversed by the rays. The rays obey absolute physical laws, and when there is any error from their use it is due to the one who uses them or the one who interprets the plate, and not to the rays. The interpretation of the plate or film is much more difficult than the making of it. For the proper interpretation of the negative one should know the conditions under which the plate was made and the appearance of the normal tissues under such conditions; also, one should in a general way be familiar with the pathologic appearance of the tissues. I believe that the best results will be accomplished if the roentgenologist and the dentist confer on each difficult plate.

The degrees of density as measured by the rays are, in order, as follows: The greatest density is shown by metallic fillings, then by root fillings; next in density is the enamel, then the dentine, and finally the cancellous structure of the maxilla and alveolar process.

The value of a roentgenograph depends very much on a careful study of details, and therefore one of the first requisites is that it show rich detail. For observing the fine lines of the tooth-structure and of the alveolar process the negative or film itself must be used, and this must be good. Much is lost in any reproduction.

THE STUDY OF THE NEGATIVE

Next in importance for reading a roentgenograph is a careful lighting of the film or negative. A uniform white light is necessary. This white light can best be obtained by means of an illumination box, or by light reflected from a sheet of white paper, or by light reflected from the northern sky. The film or negative should be surrounded by a black surface so that the eye can be concentrated on the small point of study. If attention be given to these points, almost every one can appreciate the value of the examination. Very often good negatives are condemned by untrained men, because they see little or nothing when they hold the negatives before a gas or electric lamp. This gives a yellow light and the beautiful detail is thus lost.

Read in the Section on Stomatology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

[1] Lange: Lancet-Clinic, May 16, 1908.

[2] Pfahler, G. E.: The Roentgen Rays in Oral Surgery, The Journal A. M. A., 1908, l, 432.

If studied by correct methods, the ordinary film should show that the root is smooth in contour, although it may be variously curved, and that the cancellated alveolus hugs the tooth closely. The root canal can usually be easily recognized and is smooth in outline. The dentine is normally uniform in density. The alveolar process is uniformly mottled and shows the beautiful cancellous network.

ROOTS, ROOT-ABSCESSES, EXOSTOSES, AND PULP STONES

Now, what are the pathologic appearances and conditions that may be observed? Points of decay or abscess within the root itself show an interrupting disturbance in the dentine indicated by a light area.

Incomplete filling of the root canal may be shown. A pericementitis is shown by a light space between the root surface and the alveolus, and the root surface is roughened. Abscesses about the tip of the root or in the alveolus are likewise recognized by light areas in which no cancellous structure can be made out.

Many of the cases coming before the dentist present symptoms of obscure origin; sometimes sinuses exist whose source is a riddle, and these may persist for a long time. Probing seems to be attended with some danger of spreading the infection to healthy tissues. Sometimes these abscesses follow dental work, either crowning or filling. At other times inflammation may exist simultaneously with the dental work, but in no way connected with it. The dentist will feel much relieved when it can be clearly demonstrated that his work is not responsible for the inflammation and pain. Schamberg says: "It has become an invariable rule with me to take a radiograph of every chronic abscess before performing any operation, and occasionally I take a second or third radiograph to note the progress of the case."

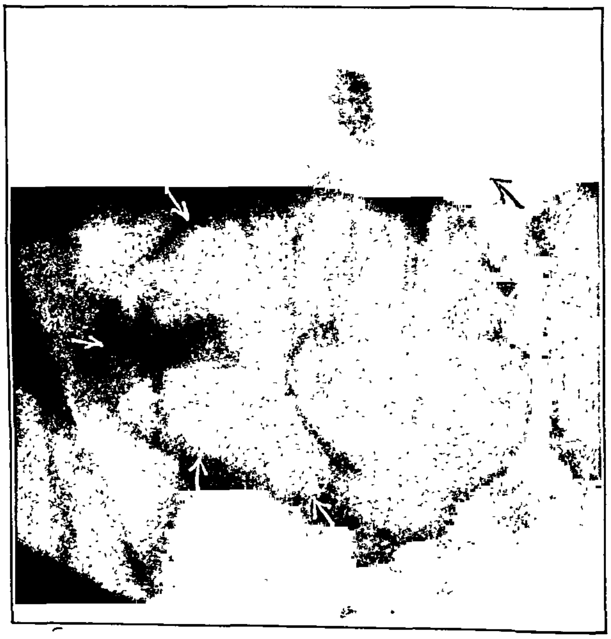

Fig. 1.—Pus in right antrum. See clear left antrum. Case of Drs. Gleason and Starr.

When men like Cryer, whose wide experience and skill in the use of the probe is recognized by all, make constant use of the rays as a diagnostic agent, its superiority over other methods can not be questioned.

The roentgenograph will make plain whether the root or only the alveolar process is involved, and consequently help to decide whether the abscess should be drained through the pulp canal or through the alveolus, and if through the alveolus whether a simple curettage would suffice or whether apical excision be necessary to eradicate the infection. Furthermore, the roentgenograph should show how much of the root should be removed. Dray says:

> Much untold suffering could be avoided, many guilty blunders obviated, many blessings bestowed on the dentist by the use, in the hands of the expert, of the x-rays. The dentist who fails to use this wonderful adjunct of modern dental diagnosis and therapeutic agency must go through life with a blunt or troubled conscience.

Lange asks:

> Would it be ultrascientific to suggest the aid of the skiagraph in all operations on the root canal? In the various manipulations on the root canal the dental surgeon is working more or less in the dark. In cleaning out such a root canal, owing to varying shapes and lengths of roots, it may be impossible to determine whether or not the apex of the root has been reached. By inserting a fine broach into the canal and skiagraphing the tooth with the broach in position this point may be cleared up. In drilling out a root canal for the insertion of a pin or post for anchorage, this same procedure will tell whether you are drilling in the right direction and whether deep enough or not.

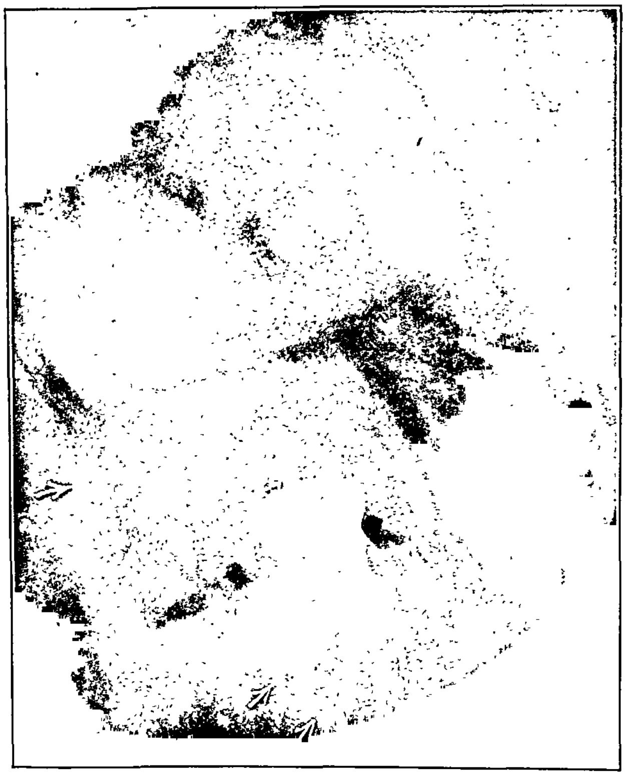

Fig. 2.—Shows cause of pus in Figure 1. Abscess about root, with pericementitis.

In several cases in which the roots were curved, I have found that the drilling extended through the side of the tooth and into the alveolar process instead of to the tip of the root canal.

Exostoses of the roots seem to be rather frequent. They cause much suffering and often explain failures in removing roots in the process of extraction.

Whorls (dense areas of bone) have been found by Cryer to explain some of the obscure cases of neuralgia.

Pulp-stones, by no means rare, cause much suffering and may be demonstrated in the roentgenographs as shown in one of my slides.

UNERUPTED, IMPACTED, SUPERNUMERARY, AND ENTIRE ABSENCE OF TEETH

One of the most important uses of the rays is the detection of unerupted, impacted, supernumerary teeth and the absence of those that should normally exist. The development and eruption of the teeth can be followed from the very beginning, and if the rays are used early the orthodontist can surely correct more easily the deformities that occur. If one follows the development of a tooth from its very incipiency, one first detects the formation of the enamel cusps, then the crown; later the root of the complete tooth with its pulp canals.

Unerupted teeth sometimes assume such freakish positions that it seems unwise to wait and guess, when we have at hand a painless and accurate means of diagnosis. Much suffering and annoyance may thus be avoided.

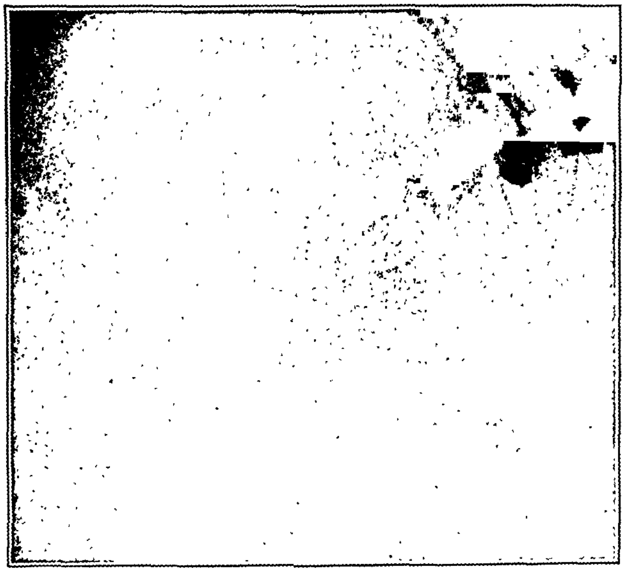

Fig. 3.—Impacted third molar. Dr. Dray's case.

Impacted teeth are rather common; the trouble affects especially the third molar, though any of the teeth may be affected. The tooth may even be inverted and be growing in the opposite direction to the normal position. These impactions usually cause great suffering and often the destruction of adjoining teeth, leading to abscess formation with surrounding inflammations, etc., which interfere with mastication and deglutition and lead to serious conditions. These impactions are often the cause of obstinate and persistent neuralgias.

All orthodontists agree that the deciduous teeth are often sacrificed too early, leading to undevelopment or later deformities of the jaws. On the other hand, a deciduous tooth often interferes with the eruption of the permanent, and causes much unnecessary suffering What other accurate guide have we in the control and observation of erupting teeth?

THE MAXILLA AND THE ACCESSORY SINUSES

The affections of the maxilla and the accessory sinuses are generally brought to the attention of the general medical or dental practitioner. If he fails to realize the possibility of disease in these areas and fails to use the roentgenograph as an aid in diagnosis, much valuable time will be lost and much unnecessary suffering will result.

In the lower jaw we must consider especially fractures, necrosis, tumor formation, and cystic degeneration. The location of a fracture is indicated by a transparent line, usually jagged in outline. Its union is indicated by the gradual disappearance of this line and by the formation of callus. Non-union is indicated by the persistence of and widening of this line and by the formation of sinuses, and often by the formation of excessive but unhealthy callus. The roentgenograph will thus aid materially in deciding on the line of treatment and especially determining whether the interdental splint should be used, or whether the case calls for the wiring procedure. If wiring be decided on the roentgenograph will indicate the best points for the drill holes. Not infrequently these fractures will be found to have been preceded by abscess formation at that location. The knowledge of the presence of an abscess will surely be important in deciding the line of treatment.

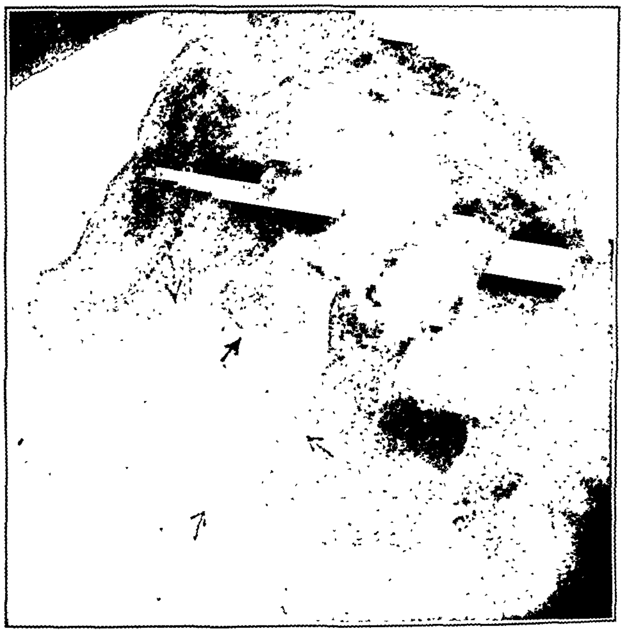

Fig. 4.—Bone cyst. See inversion of erupting teeth. Dr. Schamberg's case.

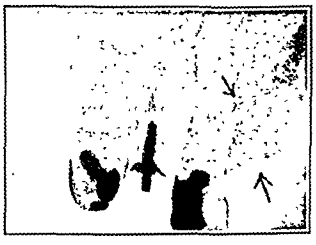

Fig. 5.—Curved incisor, showing hole drilled through the side of the tooth. Dr. Ickes' case.

Necrosis is indicated by a disturbance in the fine network of the cancellous structure of the bone, usually consisting in increased transparency due to destruction of the bony elements.

Tumors of the lower maxilla are shown by a destructive disturbance in the cancellous structure of the bone, but it is less definitely outlined than in necrosis and abscess formation, fading more gradually into the healthy bone, and is often associated with the formation of new tissue. Carcinoma seems to cause more destruction of bone and less formation of new tissue than sarcoma. Most of the tumors seem to be sarcomata and the rays will assist in determining whether only the periosteum or the bone itself is involved. The extent of the disease can also be determined and thus material assistance be secured in outlining the treatment.

Cystic degeneration in the bone is comparatively rare, but it should be borne in mind in obscure cases and it can only be accurately diagnosed by means of the rays.

If the upper jaw is involved by necrosis or the formation of a tumor, its demonstration is more difficult than the same in the lower mandible. Affections of the antrum as well as of the other accessory sinuses leading to the accumulation of pus or tumor formation can be nicely demonstrated and often the cause can be shown by the use of the *x*-ray. It is well to know whether the pus in the antrum is due to a decayed tooth or not. The *x*-ray will also show at what point the antrum should be drained; the most dependent portion of the antrum can be determined and the best drainage obtained.

THERAPEUTIC APPLICATION OF THE RAYS

The application of the rays therapeutically has been less extensive, though there have been sufficient scattered reports of good results to justify its consideration in obstinate cases and when other methods have failed.

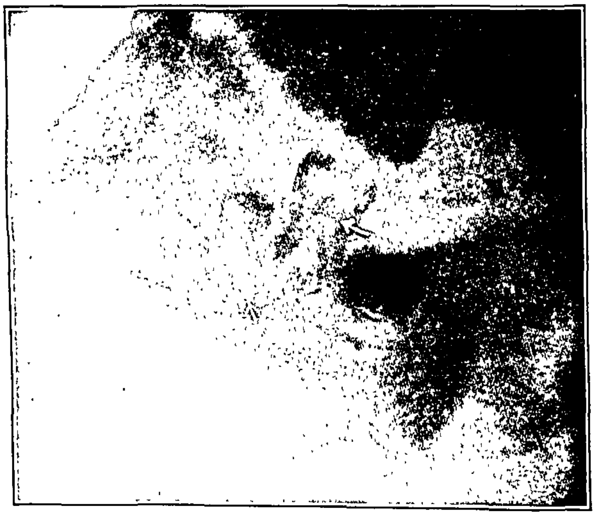

Fig. 6.—Showing pulp stone in crown, and abscesses at the root. Dr. Schamberg's case.

I have myself seen marvelous results in the treatment of sarcoma of the bones and sinuses of the face. I have seen pyorrhea of the antrum that resisted all other forms of treatment, including repeated curettement, get well under the influence of the rays. Obstinate cases of idiopathic neuralgia will sometimes yield quickly. I have seen good results in old and obstinate cases of pyorrhea alveolaris. Dr. Weston A. Price, of Cleveland, has made the best reports[3] on this subject.

CONCLUSIONS

1. There should be a more general use of this valuable diagnostic and therapeutic agent in dentistry.
2. It is without danger in the hands of an expert.
3. It is a painless, aseptic and accurate means of diagnosis.
4. All parts of the jaws can be shown on the plate. The finest details of the tooth structure and alveolar process can be best obtained by using a film within the mouth.
5. This method of diagnosis should be used in obscure cases, especially in chronic abscesses, the examination of roots and pulp canal fillings, etc., of offending teeth with persistent non-yielding pathologic conditions.

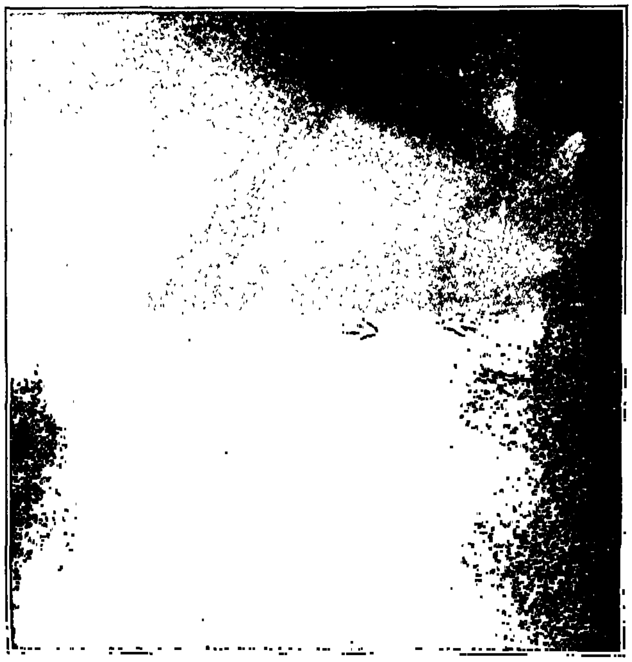

Fig. 7.—Fracture of styloid process due to pressure by dentist back of the angle of the jaw. Dr. Laplace's case.

6. The rays are particularly useful in diagnosing unerupted and impacted teeth, root abscesses and alveolar abscesses, exostoses, tumors and necrosis and, last but not least, pulp stones.

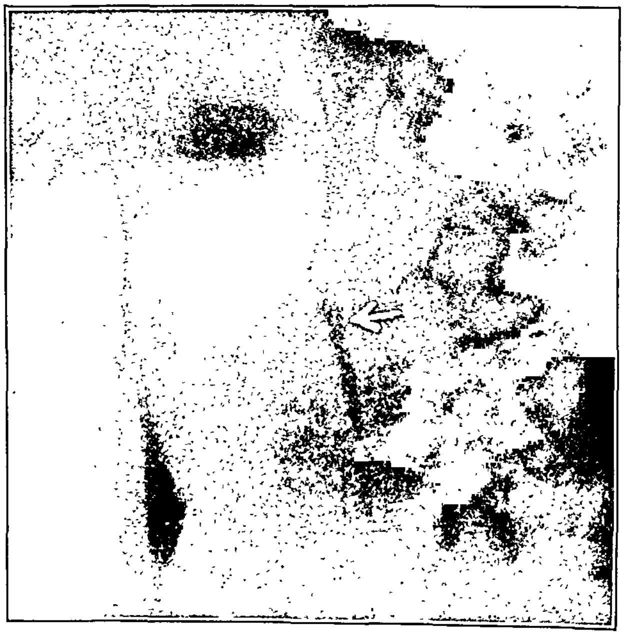

Fig. 8.—Same case as Figure 7. Healthy side. Shows abnormally long styloid process.

Finally, I desire to express my appreciation of the courtesy of Drs. Cryer, Dray, Schamberg, Cameron, Warren, Faught, Mershon, Babcock, Cupid, Bernds and Gray and others in referring these cases.

1321 Spruce Street.

---

[3] Cleveland Dental Society, Jan. 4, 1904.

ABSTRACT OF DISCUSSION

Dr. Sidney Lange, Cincinnati: The picture of the pulp stone in the pulp chamber was of especial interest to me. I have seen a number of patients with so-called facial neuralgia (for want of a better term) who had gone from dental surgeon to rhinologist and back again without getting relief. In this class of cases the *x*-ray will often indicate the source of the trouble and in not an inconsiderable number I believe the cause will be found to be a pulp stone irritating the nerve endings. The aid which the *x*-ray lends will certainly be most grateful to these patients. Another method in *x*-ray diagnosis has served me in good stead and that is the tracing of sinuses and areas of necrosis by injecting a bismuth suspension and then skiagraphing. This method is especially valuable in outlining areas of necrosis between the inner and outer plates of the alveolar processes. The picture of the fractured styloid process was a revelation to me. Attention is now being directed to injuries of this bony process and the value of the *x*-ray in this connection is inestimable.

I recall an unusually interesting case of a type not touched on by Dr. Pfahler in his demonstration. The case was one of intra-alveolar fracture of the root of the tooth from a blow on the crown. The patient complained of soreness and pain on pressure yet the tooth was apparently sound and firm. The *x*-ray revealed a transverse fracture of the root not far from its apex.

Dr. Arthur R. Dray, Philadelphia: Recently a well-known dentist of Philadelphia, talking on the subject of *x*-ray in dentistry, said something as follows: "I have been considering the use of the *x*-ray in dentistry for several years, and have come to the conclusion after an exhaustive study, that it is useless." The truth is that the *x*-ray is very valuable in dentistry, as Dr. Pfahler has most conclusively shown. First, in detection of undeveloped teeth; then in detection of impacted teeth with abscesses. The pulp stone may be detected by the *x*-ray—the neuralgic symptoms produced by other conditions are so similar to those produced by pulp stones that only the *x*-ray can determine the true cause when it is pulp stone that is the factor. The results of *x*-ray treatment in pyorrhea have been remarkable. Antral troubles, exostoses, erosion of the roots, areas of necrosis, cysts, different tumors, fractures of the jaw and the roots of teeth, can all be wonderfully cleared up by the use of the *x*-ray. In some cases—sarcomata, carcinomata, fractures, etc.—we are absolutely dependent on the *x*-ray; and last, but not least, in detecting perforation of roots and lost portions of the instruments left behind by the absent-minded dentist. We need the *x*-ray to help us to progress with modern science.

Dr. Charles K. Teter, Cleveland: I can not understand how any dentist of to-day could state that the *x*-ray is of no use in dentistry. It would be a good thing for many of the dentists if they could have the *x*-ray thrown on their work after they are through with it, especially in treating root canals. Not long ago I heard a dentist say there was not a root he could not fill to the apex. We arranged an experiment where the roots were placed in plaster and given to this dentist to fill, which was an easier proposition than it would have been in the mouth. I am not in a position to give the absolute number of teeth that were filled, but less than a fourth of the number were filled to the apex. If they could all have the *x*-ray thrown on their work afterward they would know the exact conditions. Another point: the value of the *x*-ray depends to a large extent on the manner in which the pictures are interpreted; it takes a trained man to interpret them correctly. The average man can not do it.

Dr. Arthur Zentler, New York City: Dr. William B. Dunning read a paper some time ago before the Institute of Stomatology in New York, describing a new method of filling root canals with a combination of paraform, paraffin and zinc oxid. This method, which undoubtedly is known to a good many of you, consists in melting this solid mass at the orifice of the root canals, introducing it by capillary attraction up to the apex. The question is raised whether capillary attraction will carry the melted substance to the extreme end of the roots, in which case after solidifying it would act as a permanent, good root canal filling. There is no other way of proving conclusively that it reaches the end of the root canal except by the radiograph, which in this, as in other cases mentioned by the essayist and other speakers, remains the decisive test.

Dr. Stewart L. McCurdy, Pittsburg: I have been impressed with the value of the *x*-ray as a method of making diagnosis in every branch of surgery for a great many years, and have been using it constantly. The question of *x*-ray interpretation referred to by Dr. Teter is important. It would be impossible for a man who did not know the normal anatomy of the face to interpret these pictures properly. It is only by constant and repeated readings, with the normal skull present, that these interpretations can be made correctly. The method of focusing the *x*-ray at various angles is of value in giving us a view of the entire field. The constant presentation of the subject by the men who believe in it and a campaign of education among the dentists is the only thing that will bring the *x*-ray to its proper plane of usefulness.

Dr. Arthur R. Dray, Philadelphia: There is one phase of the subject I would like to ask Dr. Pfahler to lay stress on, viz.: the all-important fact that it depends on the skill of the one who manipulates the *x*-ray apparatus whether we will discard it or accept it. This was brought to my attention forcibly some time ago. A patient was brought to me for treatment who had been told by his medical adviser that he was suffering from a malignant growth of the inferior maxillary bone. I requested an *x*-ray examination to be made by Dr. Pfahler. It showed what I had suspected, an encysted unerupted tooth. The patient was about 70 years of age and gave a history of the teeth having been removed years previously, thus throwing the medical man off his guard.

I found out months afterward in talking with this patient that an *x*-ray picture had been taken of this same case, before Dr. Pfahler examined him, which did not show anything of the encysted tooth so clearly demonstrated in the second picture.

Dr. G. E. Pfahler, Philadelphia: The only safe way is to have the work done by a man who is thoroughly competent. I think that poor work in this line is worse than none at all. The dentist and the *x*-ray man should work together. The dentist should give all the information he can as to the probable location of the lesion. After the picture has been taken, I always try to have a conference with the dentist, either by sending in my report with the plate and discussing it afterward, or by meeting and conferring personally. While many negatives are clear in diagnosis and could be read by any one, others are obscure and could only be safely interpreted by conference.

RECONSTRUCTION OF THE BILE DUCTS *

ARTHUR G. SULLIVAN, M.D.
Senior Assistant, Surgical Research Laboratory, Columbia College of Physicians and Surgeons
NEW YORK

This paper is an outgrowth from one branch of work done for Dr. J. W. D. Maury (Associate in charge of Surgical Laboratory) in his search for the cause of death in high intestinal obstruction.

The available literature fails to reveal a method for the construction of an intra-abdominal sinus for biliary drainage. This procedure depends on the use of a rubber tube, at one end of which a rubber sponge, or an ordinary surgical sponge, is securely attached (Fig. 1). The tube should be approximately the size of the common bile duct, and the diameter of the sponge should not be greater than one-half the diameter of the duodenal lumen. The length of the tube depends on the length of the biliary passage to be reconstructed.

The operative technic followed in this experimental work is roughly as follows: The common bile duct is exposed, ligated and cut across just above the ligature. Two plain catgut No. 1 sutures are introduced in the opposite edges of the gaping duct, and in the rubber tube, in such a manner that when the sutures are tied down, the knots will be on opposite surfaces of the duct, and the tube drawn within the lumen of the duct a distance of approximately 1 cm. (Fig. 2). The tube is then applied to the anterior surface of the duodenum (Fig. 4), and at approximately every inch is sutured to the duodenal wall with fine catgut. At a point about opposite the ampulla of Vater, an incision is made in the duodenum, just large enough to allow the insertion of the sponge and attached tube into the lumen of the intestine. The sponge is shoved down inside the intestine, and the opening in the duodenum is sufficiently repaired so that the cut edges snugly encircle the tube. At this point—where the tube penetrates the intestinal wall—a No. 1 plain catgut suture is inserted, taking a good bite of duodenum and a small bite of the tube, so as not to encroach on the lumen of the tube. This suture does two things—it prevents the peristaltic pull on the sponge from tearing the two duct sutures free, and it minimizes biliary colic, as has been demonstrated in dogs. The duodenal walls are then sutured over the tube so that for about 2 cm. before the tube penetrates into the intestine, it runs in a canal made by overlapped duodenum. The great omentum is then drawn up, and a suitable area selected with which to cover the exposed portion of the tube. This area is traumatized by slightly drawing a dry sponge over it a few times, and similar friction is applied to the duodenum and gastro-hepatic omentum on either side of the tube. The omentum is then placed so as to cover the tube and extend beyond it a centimeter or two in all directions, and is held in position by several fine catgut sutures (Fig. 5).

Eight dogs have been operated on in this manner, and the following facts observed:

Dog 1 was operated on eleven weeks ago, and a plain tube, without sponge attached, was used. Fifteen days later his abdomen was again opened, and the tube drawn out through a buttonhole incision in the duodenum. The ease with which the tube slipped out suggested that the peristaltic action of the intestine could well supplant the second operative procedures.

Dog 2 was operated on nine weeks ago, and a tube with a rubber sponge tipped end was inserted. Owing to my anxiety to have the peristalsis fulfil anticipation, I used very fine plain catgut throughout (No. 00), with the result that tube and sponge were passed sixty hours later. No harm resulted, however.

Dog 3 was operated on seven weeks ago. The rubbber sponge was passed two days later, it having torn from the tube because of faulty ligation. Consequently the tube itself was removed several days afterward, through very small incisions in the abdominal wall and duodenum, as in Dog 1.

Dog 4 had a tube and rubber sponge inserted in him five weeks ago, and passed both intact seven days later.

It occurred to me that a rubber sponge might not be procurable in case of emergency, and consequently I took a surgical sponge, stitched it so that it would not unfold, sutured it to a rubber tube, and introduced it into the next subject.

Dog 5 had the surgical sponge and rubber tube inserted, and eight days later tube and sponge were passed.

Dogs 6 and 7 were operated on three weeks ago, and *Dog 8* two weeks ago. Cholecystectomy was done in all three, and hepaticus was connected with the duodenum, the usual technic being employed. Dog 6 passed his tube on the eighth day, Dog 7 on the sixth day and Dog 8 was killed by ether a few days after his operation to secure a specimen (Fig. 6), which shows the tube *in situ*, connecting hepaticus and duodenum, with the gall bladder removed.

Another specimen (Fig. 7) was taken from Dog 5 two days after he passed the gauze sponge and tube. From the latter specimen several microscopic sections were taken and the pathologist reported that the mucosa had grown upward from the duodenum, and downward from the duct, into the new formed tube. At its middle part the walls are composed of peritoneal tissue. There is absolutely no evidence of inflammatory deposit. It will be noted, as shown in Figure 3, that the new-formed tube is made up of peritoneal tissue in its entire extent.

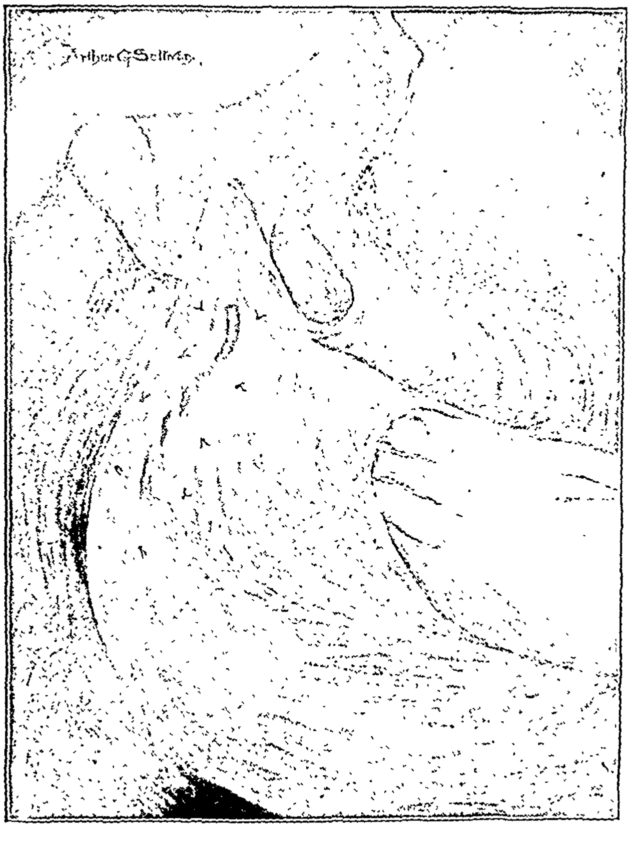

Fig. 5.—Great omentum drawn up and sutured to form anterior wall of reconstructed passage.

Nothing which could be called unusual postoperative care was given these animals. Their regular diet was allowed them within thirty hours, and yet all, save those from which specimens were removed, are delivering bile in normal amounts, to say nothing of being alive, well, and in the best of spirits. Careful watch was kept of all feces and no sign of acholia appeared, nor was there a symptom of leakage or peritonitis.

On analyzing the constituent steps in this work, it is at once apparent that the operation is merely a combination of more or less accepted technical details. The drainage of the hepatic duct by rubber tube, set forth by Abbe, is recognized. Witzel's method of gastrostomy is roughly similar to my method of implanting the tube in the duodenum. Kehr has successfully used gastric wall to bridge over a deficiency in the wall of the common duct; and the use of omental grafts to cover such apertures is a fairly common proceeding.

For the benefit of those who might feel inclined to perform this experiment on dogs, I wish to emphasize the necessary steps.

1. It is essential that the tube be placed within the duct, and not in the reverse order.
2. The duodenal wall must be folded over the tube for a distance of 2 cm. before it plunges into the lumen of the intestine.
3. The restraining stitch, which temporarily prevents traction on the upper portion of the tube, should be put in.
4. The tissues forming the walls of the tube must be lightly traumatized.
5. The sponge should not occupy more than half the lumen of the intestine and especially when a gauze sponge is used.
6. In case cholecystectomy is done, the gall bladder fossa should be obliterated by stitching the lobes of the liver together, thus avoiding hemorrhage, which is difficult to control in dogs.

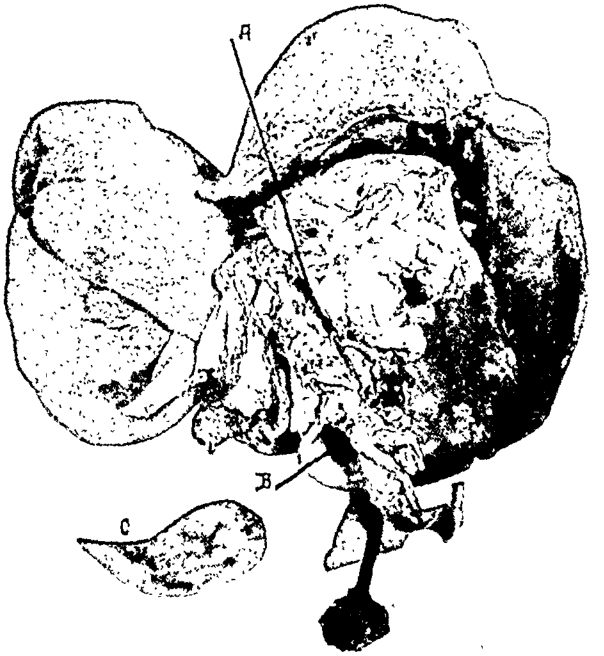

Fig. 6.—Specimen from Dog 8. A, omentum cut away to expose tube; B, duodenal lumen; C, gall bladder.

In the last two operations, the sponge which was inserted was compressed as much as possible, by taking several turns of No. 3 plain catgut around it. My experience has been that catgut in the lumen of the dog's duodenum is disintegrated about three times as rapidly as that placed in the body tissues. So by using the heavier gut, with which to compress the sponge, one very greatly diminishes the peristaltic tug on the tube for a few days after the operation, until finally the sponge breaks its bonds, expands, and is then ready to do active work at approximately the same time that the catgut holding the tube in the duct is absorbed. The advantage of having the tube undisturbed the first few days is obvious. I have one dog which was operated on 104 days ago. At that time I put a tube in him with the idea of keeping it *in situ* permanently. He is in the best of health and no signs of discomfort from the tube are apparent.

This is the "reconstruction of the bile ducts," an operation which I believe involves a new surgical principle. If the dogs survive a month or two longer without untow- [illegible] resent the same, or more favorable [illegible]. then as now, I advocate this technic in persons requiring artificial connection between the biliary passages and the intestine.

If a single hepatic duct, or the common hepatic duct, needs repair, a small tube, properly fenestrated so that it will not occlude the biliary tributaries, or the duct of Wirsung, might be passed from within the duodenum through the ampulla of Vater, up the common duct to the point where reconstruction is desired. This would more closely approximate normal conditions.

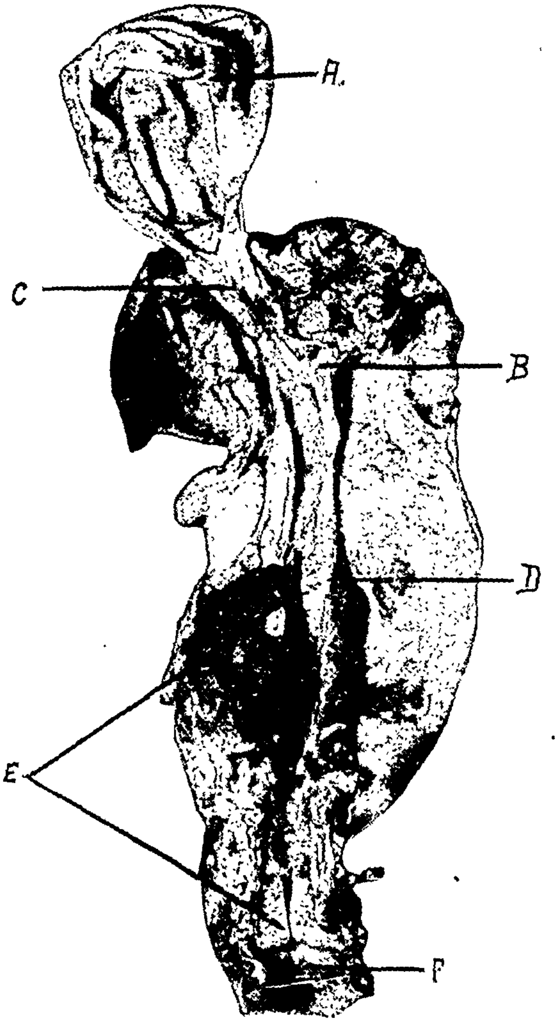

Fig. 7.—Specimen from Dog 5.—The aperture in the floor of the reconstructed duct, just as it enters the duodenum, is the result of a section taken for microscopic examination. A, interior of gall bladder; B, hepaticus; C, cysticus; D, end of common bile duct; E, reconstructed duct; F, duodenal lumen.

SUMMARY

1. There is no technic for duct reconstruction in general use.
2. In the operation described the reconstructed canal is made of formed tissues, rather than inflammatory deposits.
3. Both ends are protected by mucosa.
4. There was no mortality in eight cases.

I am much indebted to Drs. H. H. Janeway and J. W. D. Maury for their kind aid.

EXPERIENCE IN THE EXPRESSION OF CATARACTS IN THE CAPSULE BY THE SMITH METHOD *

D. W. GREENE, M.D.
DAYTON, OHIO

When Major Smith's article[1] on the extraction of cataract within the capsule by external manipulation appeared I became interested in the possibilities of the method and gave it such trial as I was capable of at that time in twenty-two cases. These were hastily brought together and not selected. The results were thought to be not satisfactory at the time and were so reported,[2] but further observation has shown that a very fair percentage of the patients did well. In the beginning it should be stated that I have only included in these later statistics cases of operation in which I have supervised the after-treatment and determined the refraction.

Of all the operations which have been proposed for the removal of cataract, no one of them and no combination of them offers such a complete and satisfactory disposition of the capsule, which is the beginning, middle and end of most of our after-troubles, as extraction within the capsule.[3] This is so evident that if any added risk is incurred in doing the operation it seems more than offset by what is gained in the comparative freedom from the complications which are liable to follow the regular operation. Regarding these complications, Knapp long ago called attention to the fact that iridectomy alone was a comparatively safe procedure, but that opening the capsule and extracting the lens added other elements of danger to the traumatism of the iridectomy, and changed the condition to one of danger to the eye in a certain proportion of cases. These elements of danger consisted in the mechanical irritation of the lens débris to the cut and torn surface of the iris[4] Hess and Schirmer regard this irritation as due to infection.[5] "It seems more than probable that the inflammation is due to the chemically altered lens substance which acts as an irritant, but whether it is trauma, infection or chemical irritation, it is generally acknowledged that the postoperative dangers—iritis, cyclitis or iridocyclitis—are in some manner attributable to the cortical débris."[6] If the true explanation of the causes of these postoperative inflammations is to be found in either of these theories, such sequelæ should not follow delivery in the capsule, and experience shows that delivery in the capsule furnishes a high degree of immunity from them. The combined operation, in the hands of the best operators of this and other countries in 1,032 operations, according to Ring, furnished a loss of vitreous in 7.23 per cent., iritis in 13.15 per cent., incarceration of iris in 4.32 per cent., and discission was required in 26.61 per cent.[7] According to Smith's statistics three years ago, in 2,616 operations he only had 6.8 per cent. of loss of vitreous and 0.3 per cent. of iritis in 2,494 operations when the lens came

away whole, but when the capsule was opened intentionally or ruptured in delivery, and had to be left behind, iritis was observed in 5 per cent. of the cases.[8] Dr. Arnold Knapp, after a visit to Major Smith's clinic at Jullundur in 1906,[9] practically confirmed these statistics. We must, therefore, accept these percentages and seek their explanation in the marvelous skill of the operator and the comparatively early age at which cataracts develop in India. Cases of cataract, I understand, develop in persons between five and ten years younger in India than in this country. The degenerative changes of the vitreous are more marked in the ten years between sixty and seventy than at any prior period, and the condition of the vitreous is the essential all-important element which influences statistics as to its loss, the shape of the pupil, iris entanglements, etc., in the operation.

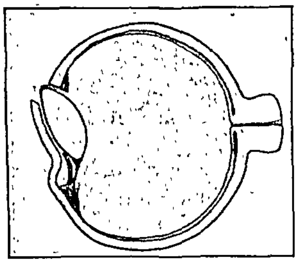

Fig. 1.

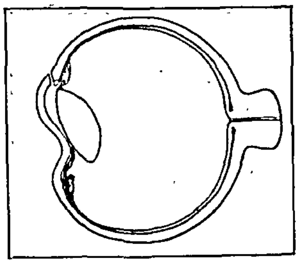

Fig. 2.

Fig. 1.—These figures are a schematic representation of the accouchement of the lens in its capsule. Fig. 1 shows the indentation of the cornea and zonula below and the slight protrusion of the lens above.

Fig. 2.—Rupture of the zonula below and lens dropping back.

Attention is called to the fact that the average age of my patients has been high (67.7 years). Largely because of this I think my percentage of vitreous loss has been high also. In making these later operations I had the advantage of having seen Smith perform it; I have learned by experience that the percentage of success depends more on the attainment of a high degree of skill, technical knowledge and the imitative faculty than on any skill acquired in making the regular operation. Theoretical considerations avail little or nothing in considering its place among cataract operations. The operation can be learned only at the elbow of one who is capable of demonstrating it. Without having this advantage and experience in the after-treatment of cases, no one is capable of passing judgment on the merits or demerits of the operation.

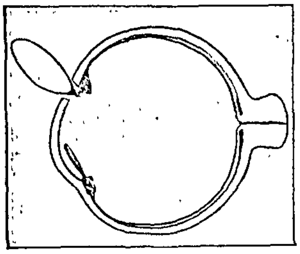

Fig. 5.—Lens almost delivered.

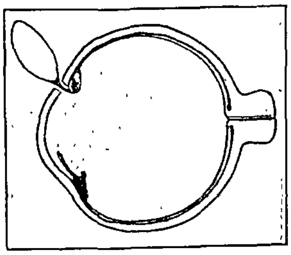

Fig. 6.

Fig. 6.—Lens is wholly out but is held by some of the superior fibers of the zonula. These fibers are torn by a slight lateral rocking motion of the lens produced by the use of the hook. The lens is now delivered in its capsule.

In July of last year, through the courtesy of Dr. Arnold Knapp, I saw Major Smith make three operations in New York City. So large a crowd was present that my view of the operations was not satisfactory, but I afterward spent several hours with him listening to descriptions of his method and seeing him demonstrate it until I thought I had a fair understanding of his technic. Major Smith regards the operation as in process of evolution. I quote from a late letter: "When once we have convinced ourselves that we are right, and have the doggedness to go ahead, our ultimate success is assured." Again he says: "You can not teach a man to do this operation by mere demonstration. He must do the operation before the teacher sufficiently often to acquire confidence in himself; and, further, a trained assistant who can properly expose the eye and at the same time take off all pressure is scarcely less important to the success of the operation than the operator himself." In this connection his address[10] before the American Ophthalmological Society at New London, Conn., last July, should be read. After describing the operation, he says:

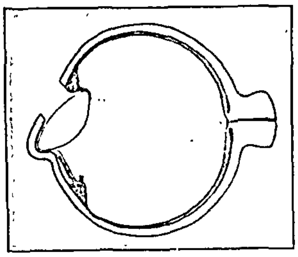

Fig. 3.

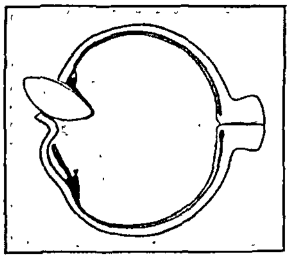

Fig. 4.

Fig. 3.—Lens is beginning to turn. The hook alone is used now and follows up the lens.

Fig. 4.—The lens has turned and is partially delivered.

> The treatment of immature cataracts which I have practiced extensively, and which I am an ardent advocate of, which I regard as the operation of the future, which will leave senile cataract a much rarer condition than at present, is extraction of the lens in the capsule, a procedure to which immature cataracts are admirably suited. *I hold that, if for no other reason than for the treatment of immature cataract, every ophthalmic surgeon should be familiar with the art of extracting the cataractous lens in its capsule.*

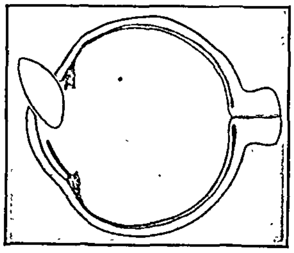

Fig. 7.—Shows the delivery of the lens in the capsule when the superior fibers of the zonula give way at the same time that the inferior fibers do. This occurs in 15 to 20 per cent. of all cases. It is in these cases that the loss of vitreous is most frequent, and that the spoon is sometimes inserted in the wound above to aid in the delivery.

I submit with diffidence that three years ago I called attention to these same points in the treatment of immature cataract,[11] and further experience has confirmed my belief that the method is superior to any other method of extracting such cataracts, or to any method of artificial ripening. It is in the treatment of immature cataract that I think the Smith operation will receive its first recognition, because, if I understand the opinion of the profession on this point, it is not favorable to extracting unripe cataracts by regular methods. Major Smith has told me that just this line of reasoning and observation with capsulotomy methods and secondary operations and accidental deliveries in the capsule are what led him to seek a method of delivering all kinds of cataracts, which would at the same time remove the capsule with the lens, because he believes such disposition of it to be good surgery.

[11] Ophthalmology, January, 1907.

While writers from the time of Pagenstecher to the present have considered hypermature cataracts specially suited for removal in the capsule, my experience has been that these are usually the most difficult to express. The vitreous is often fluid, the strength of the zonula, while usually frail, can not be foretold, and the milky cortex will be forced by the pressure to occupy one end of the capsular bag and the small disc-like nucleus will float to the other. I have seen this hour-glass appearance several times. These are the cases which require careful handling, since they furnish a high percentage of loss of vitreous, but the same would be true if extractions were done by regular methods. In this connection we should remember that cataractous eyes are always diseased eyes, as Risley and others have so well shown. While it is my desire to discuss the operation from my personal experience, I recognize the difficulty of placing my experience, which is limited, but, on the whole, *is favorable to the Smith operation,* in opposition to the theoretical considerations which have influenced men against delivery in the capsule, and for comparison with the vast number of reports of regular operations and published statistics by innumerable observers there are no extensive statistics of delivery in the capsule available. The fact that possibly but one operation in the capsule to five thousand or more by capsulotomy methods has been made, ought not, *per se,* to prejudice men against accepting a new procedure which, to say the least, is theoretically desirable, because from the beginning the desire of the profession has been for a method which would remove the capsule with the lens. All have recognized the undesirability of leaving it behind and the surgical incompleteness of all operations which do so. Witness the early efforts of Richter and Beer, the later efforts of Sperino and de Wecker, and the still later method of Pagenstecher and Macnamara to accomplish this end. Loss of vitreous, as a rule, in my experience, has been more the fault of the patient than of the operation. This statement does not help the matter, but it puts the blame where it usually belongs.

The fear of retinal detachment from loss of vitreous seems to be the *bête noir* of all men with whom I have discussed the operation, yet this danger is not supported by the available statistics, and it really seems to be very small. Pagenstecher more than forty years ago, in 600 operations, saw only one case of detachment of the retina, and that in a highly myopic eye with chorioiditis. Wetzel and Beer long ago stated that they had not seen harm resulting from a loss of one-third of the vitreous (by volume). Smith has stated that in his experience the same is true. Captain Lister of the Indian Medical Service, a former pupil of Major Smith's, has examined 100 cases of from one to seven years after loss of vitreous. He read a report at the Bombay Medical Congress in February; his conclusions have not yet been published, but Smith has stated that Lister did not find a case of detachment of the retina among them. It must, however, be admitted in this connection that loss of vitreous is looked on by the majority of men in this country with apprehension. Whether they overestimated its importance or not, time and observation alone can tell. I myself have seen only two cases in which vision following the operation merely equaled perception of light, which could be attributed to detachment of the retina after the loss of about one-half of the vitreous. In these cases there was delayed healing, gaping of the wound and an ingrowth of corneal epithelium, and reduction in size of the cornea in healing, so that no view of the fundus could be had. I have not been certain as to the cause of loss of vision in these cases because P. L. remained. Several times after a slight loss of vitreous I have smoothed out the iris and have seen many cases in which it would be impossible to tell that the lens had been removed in the capsule. On the other hand, in a few instances I have bandaged up an eye with a keyhole pupil and have found the wound open, vitreous presenting and the iris entangled in the angles at the first dressing. The same condition is observed after the regular operations. These conditions are usually observed in nervous and restless patients with high blood pressure.

Loss of vitreous should not be the sole measure by which the operation is judged; if it is as serious as many think, the danger is yet to be proved. The statistics we have do not prove the danger to be great, and Smith's statistics show that with select cases it is possible to reduce it to the percentage of the regular operation or even below it. Surely comparative freedom from inflammation and high-class visual results count for more than slight loss.

Perhaps of more importance to the future integrity of the eye than loss of vitreous is the fact that no discission is necessary. It requires no argument to show that the risk of an operation increases in proportion to the number of times a knife-needle or scissors are passed into the eye. This is also one of the essential points on which those favorable to the Smith operation based their contention, *that it is both safer and more complete than the regular operation,* even if the loss of vitreous is greater for the average operator, *which must be conceded.* This liability to accident seems more than offset by the comparative infrequency of the reactions that are liable to follow a discission. Having had a large experience with extraction and after-treatment with capsulotomy methods, I have not seen such smooth and uncomplicated healing, all things being equal, in any other series of cases; there can be no question as to the correctness of this observation, and it is in harmony with the experience of all who are familiar with delivery within the capsule. On this point I do not wish to be misunderstood. I have encountered certain reactions, but they have not been of an inflammatory character (except in the few cases shown in the statistics), but have been connected with the healing of the section and have usually been associated with ruptures of the capsule, incarceration of iris, or cystoid healing, and blood pressure above 160 mm. Hg. in nervous and restless patients. Only two cases of iritis sufficient to cause pain and require treatment have been observed. Both followed rupture of the capsule. A few times I have observed the intrusion of a bead of vitreous into the section at the first dressing, or even later when none had presented at the time of operation. It has not been sufficient as a rule to abscise it because more will take its place, but I have always secured firm union by repeatedly tapping the chamber below, and the same practice has been successful in cystoid healing after excising the cyst.

My experience with the operation has been largely with patients of advanced years in my clinic at the National Military Home, at St. Elizabeth's Hospital, this city (and in private practice) in whom the conditions of the vitreous and fundus are frequently unfavorable to high-class results.

I pass rapidly over the corneal incision, which should be an enlarged de Wecker without a corneal flap. I have tried making a large iridectomy, and have found it to have some advantages in the delivery of the lens, but, on the other hand, as the tendency is in the direction of too large a pupil, I have made a small iridectomy as a rule. The patient can look down during the completion of the section and the iridectomy, but during the expression of the lens must look straight ahead or slightly upward, *never downward.* I have seen more loss of vitreous from the patient violating this injunction than from any other cause.

Smith's late manipulation with the end of the spatula and strabismus hook, over the lower third of the lens, by which it is dislocated, has been the most difficult step to imitate. I am conscious that failure to make this manipulation properly has been the weak point in my technic, and has materially increased my percentage of vitreous loss. I have dispensed entirely with the speculum while making the section and the iridectomy and have had my assistants use the Fisher and later the Noyes lid-elevator instead. The assistant changes to the large hook after the iridectomy, and lifts the upper lid as Smith has directed. The operator should make light or moderate pressure to and fro over the lower third of the lens with the tip of the strabismus hook. At this stage the operator will see the lower border of the lens mapped out through the cornea and iris advanced slightly, then with moderate pressure with the small end of the spatula applied edgewise across the lower sclerocorneal border the lens will advance still farther toward the incision, the zonula will give way, and the top of the lens will often tilt slightly backward. If the pressure is continued around the lower border of the lens, and the tip of the hook inserted under or behind it, the intraocular pressure will aid in causing the lens, which is now only anchored above, to describe a half-circle. The wound will gape, and the lens will emerge bottom edge upward, leaving only a small band of zonula to be loosened. This must be done slowly and with the utmost gentleness by drawing it back and forth through the incision. Otherwise the capsule will rupture and recede into the eye. It is still possible to catch it with forceps if the operator be dextrous. Vitreous is seldom lost when the lens is delivered in this way. In more than half of these cases the lens has been delivered thus. In other cases the zonula will rupture first at one of the angles of the section; then if the vitreous is fluid some of it is easily lost. It is at this point that familiarity with what may happen and skill and technic in meeting the emergency obviates some mishaps.

Before leaving these steps in operation I wish to call attention to the perfect control the assistant has over the orbicularis with the large strabismus hook under the upper lid. Slight traction with it will break the power of the muscle by bending it at a sharp angle. With a small piece of gauze on the face of his thumb the assistant pulls down the lower lid. With a trained assistant it is practically impossible for the patient to squeeze out normal vitreous. Unfortunately not all patients have normal vitreous and it is easy for the patient to lose fluid vitreous not only by attempts at squeezing but by suddenly and forcibly looking down. So far as I am able to learn, the particular design of this large hook, and the use to which it is put, the control of the lower lid in the way described and the use of the smaller hook for delivering the lens, must be credited to Major Smith. To his credit also, I think, belong the manipulation in emergencies with the double-ended spatula, one end of which is passed through the vitreous presenting behind the lens. It should not be passed deeper than the posterior pole of the lens, while pressure through the cornea below will cause the lens in its capsule to glide up this inclined plane to its exit. In my judgment these three instruments are the best additions that have been made to the armamentarium of the ophthalmic surgeon in many years. Since I have been making more pressure with the tip of the spatula and done less rubbing over the lower third of the lens the number of cases of striped and latticed keratitis have markedly diminished, and I have not seen either remain and lower vision in any of these cases. I never use bichlorid solution in cataract operations; therefore it could not be responsible for the keratitis. There are no rules governing the amount of pressure to be used in delivering the lens. Each case is a law unto itself. Three points should be remembered: 1. The pressure should never be excessive, but steady and equal. 2. The cornea should be kept moist. 3. There should be no pressure or rubbing over the center of the cornea.

It is in connection with these manipulations that men become prejudiced against the operation when they see it performed for the first time, because they overestimate the force of the steady pressure required to rupture the zonula and dislocate the lens, and consider the manipulations rough and unscientific. I have satisfied several who have visited my clinics that the degree of pressure used is not great, but is much more apparent than real. In other words, they have unlearned some of their misconceptions regarding this important step of the operation.

The lens having been delivered, the iris, if prolapsed, should be returned and smoothed out, but the danger of loss of vitreous should not be forgotten in doing this. Usually it is best to bandage the eye as soon as possible. Intrusion of fluid vitreous into the wound has not influenced the healing materially. The toilet should be made according to the taste of the operator. I prefer a half-round dry cotton patch between layers of gauze laid on the closed lids of each eye. The irregularities are filled out with small pledgets of picked cotton which are held in place by pieces of adhesive straps. I prefer a flannel bandage for the class of patients on whom most of my operations have been performed—old soldiers, many of them feeble in mind and body, bad subjects, as a rule, for any operation. The eye should not be open for three or four days unless the patient complains of pain, which is so exceedingly rare that freedom from discomfort or pain can be regarded as one of the striking characteristics of the method. On removing the dressing freedom from discharge and the normal appearance of the eyelid are usually noticeable. As a rule, the wound will be found closed and the chamber established at this first dressing; if not closed the usual conditions will be found present. The appearance of the clear black pupil is very gratifying and the distinct tracery and pattern of the iris, and its response to atropin, if used, shows its freedom from inflammation. The conjunctiva usually takes on a blush of irritation or congestion. Rarely will the deep redness and chemosis of inflammation be seen. The amount of photophobia and lachrymation will vary with the condition of the wound. I have seen only two cases of genuine iritis in these seventy-five cases. In each the capsule had ruptured and only two scissors operations have been made for up-drawn pupils in these same cases. Striped and latticed keratitis have caused more uneasiness and required more treatment than any other complication, yet, as already stated, I have not seen either remain and lower vision in any of these cases, and the same can be said of disturbance in the epithelial layer of the cornea from the pressure.

As a rule vision is not high at first, because of ker-

Table of Results of Smith Operation in 75 Cases

atitis in some cases, but more often from disturbance in the anterior layers of the vitreous which resemble miniature ridges and valleys, running perpendicularly. These have not the appearance of striped keratitis. Pagenstecher noted this condition.[12] They seem to smooth down gradually and vision reaches its best in from one to two months. The degree of astigmatism, which is usually from 2 to 4 D., has not varied much with the healing, when primary union has taken place.

For the purpose of comparing the results obtained with the combined method of extraction, I have appended the statistics of the last 75 operations in the Soldiers' Home Hospital, with the statistics of 75 cases in which operation was done by the Smith method; 52 of them in the Soldiers' Home Hospital and 23 in St. Elizabeth's Hospital. The conditions have been as uniform as possible. The average age of the patients operated on by the regular method was 69.76, and for the Smith operation 67.7 years. The number of patients operated on by each method is too small to draw any definite conclusions from, yet they are believed to have sufficient value to justify comparing them.

Expression within the capsule offers the following advantages:

1. A cataract can be removed at any stage.
2. No discission is ever necessary.
3. There is comparative freedom from postoperative inflammations.
4. There are no capsule entanglements; prompt healing is the rule.
5. The method is especially adapted to institutional work; one operation does all.
6. No ripening methods need be tried.
7. The result is better average vision, which does not change with time, if the fundus conditions remain favorable.

The disadvantages of the method are the following:

1. The only important one is greater liability to loss of vitreous for the average operator.
2. From a cosmetic point of view the wide updrawn pupil (if it results) mars the appearance of the eye, while it may not be a disadvantage to vision.
3. And lastly, a skilled assistant is always necessary in performing the operation.

It is not my desire to be considered a champion of the Smith operation until I have seen more of the ultimate results which follow it, among white people, living under different climatic and dietetic conditions than average Indians, but having emphasized its strong points, and admitted its weak points as I have seen them, I can not avoid the conclusion that it is a long step toward the ideal operation which we are all seeking. Perhaps it will not be so in the hands of every one, but in the hands of the few who will learn to do it well I believe it has a promising future. The statistics which follow have been compiled by my hospital associate, Dr. J. W. Millette. It is a pleasure to acknowledge the thorough and careful manner with which it has been done.

These statistics do not include all the operations I have performed. Cases have not been selected, but I have excluded all cases in which I have not given the after-treatment and done the testing for vision and also those cases which from the condition of the cornea, vitreous and fundus, were not proper ones from a visual point of view. Two patients whose cases were considered proper had excessive loss of vitreous and vision only equal to P.L., which are fairly chargeable to the operation; one has dense vitreous opacities, probably from hemorrhage, the other lost about half of the vitreous. He has an up-drawn pupil, and no view of the fundus can be had. I am not certain as to the cause of the loss of vision in either case, and one other case was lost from infection.

75 Average vision	20/40

One patient had slight loss of vitreous; 2 had slight attacks of glaucoma; 20 had a degree of iritis requiring treatment; 35 eyes required discission; 9 patients whose eyes needed discission refused it; 1 eye was lost by iridopyelitis after a secondary operation.

THE EXPRESSION OF CATARACT IN ITS CAPSULE

WITH REPORT OF FORTY OPERATIONS *

H. V. WÜRDEMANN, M.D.
SEATTLE, WASH.

Delivery of the lens in its capsule has been an occasional accidental accompaniment of the cataract operation experienced by most operators ever since the beginning of cataract extraction, by reason of unwonted pressure on the globe by the operator or by the patient squeezing his lids (Case 10), during which more or less vitreous has been lost. It may also be occasioned knowingly, though unwillingly, by reason of rupture of the zonula after incision of the cornea when the operator has passed a spoon behind the lens lifting it out, or when he has premeditatedly removed a dislocated lens by the same means. Over-ripe and Morgagnian cataracts have occasionally likewise been removed by much the same procedure. Those of us who have been operating for a score of years will doubtless remember many such experiences and our surprise at the unusually good visual results obtained even in some instances in which considerable vitreous was lost. The deliberate routine extraction of all senile cataracts in their capsules was first introduced by A. Pagenstecher (September, 1865) at the Heidelberg Ophthalmological Congress and has been followed since that time by him and his brother, H. Pagenstecher[1] in a large proportion of their cataract operations.

---

[12] Ann. d'ocul., September-October, 1871.

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Nach dem Drittelbogenschitt nach oben mit Bindehautlappen wird iridectomiert und hierauf die Linse, entweder durch das blosse Druckmanöver oder mit dem flachen Löffel der bloss als gleitfläche dient, entbunden.[2]

The lens is expelled after incision of about one-third of the circumference made with a conjunctival flap and an upward iridectomy, either by means of gentle pressure or with the flat spoon acting purely as a gliding surface.

The above description of Pagenstecher's operation on cataract in the unopened capsule is as short and accurate as has yet been given. Examine these words closely, the various essays of Pagenstecher, digest them, then follow up by reading the essays of subsequent writers as Cassiani,[3] Gradenigo,[4] Gayet,[5] Landesberg,[6] and other foreign authors, Roosa,[7] Andrew,[8] Henry Smith,[9] Oxley,[10] Maynard,[11] Herbert,[12] Cheney[13] and Greene,[14] then come back to the original of Pagenstecher and give credit for the devising of this operation in all its details where it belongs, not to later operators, even though of astounding skill, sufficiency and experience.

The recent revival from the antipodes has awakened new interest in this operation, largely occasioned by the astounding number of cases reported by Major Smith, of Jullundur, India, who has had an experience of about 20,000 operations, about 17,000 being in the capsule, among them many incipient cataracts.[9] While this vast experience has authoritatively established expression as successfully applied to the removal of senile cataract, yet the method should not be denominated "Smith's operation," even though he claims "the details of the operation are my own"[9] and has been accorded these claims in some quarters. In common with Major Herbert, I fail to see any substantial reason for such claims. "The operation is merely ordinary combined extraction, with the omission of one step—the opening of the capsule" (Herbert).[12] Smith insists that men must see it done in order to learn the method completely. By examination of the literature we "find no detail which has not been practiced earlier by others." "Those who have seen Smith operate do not appear to have benefited much, judging from their results" (Herbert).[12] I have not yet had the opportunity of seeing this master hand at work, but his writings certainly do not give us anything beyond the "omission of detail" (Herbert).[12]

I find nothing original except the use of the large squint hook for delivery of the lens, a minor and useful adjunct, but one which I have myself used since 1888, and probably many others have used a similar instrument for this purpose. A. and H. Pagenstecher have used a curved spoon since 1865. The large old-fashioned rounded strabismus hook is a perfectly adapted instrument for this purpose—its convexity indents the cornea properly and its concavity follows up the cataract until delivery through the open wound is completed, with much less force than by finger pressure through the lid, with more dexterity than by use of the Pagenstecher spoon, and with much less danger of bursting the hyaloid membrane and consequent prolapse of vitreous.

Until I got the Smith hook I used a crochet hook which I devised in 1889 (but never reported) for ocular muscle operations. Last year (1908) I devised a large hook with a blunt crochet end. The latter is useful just as the lens is being delivered, to lift it out of the wound. Smith's new spoon is very like the old spoon of Pagenstecher; comparison of the two will not show any appreciable difference. In common with others I believed for many years that the insertion of the spoon behind the lens or into the vitreous back of the hyaloid membrane was the distinguishing mark of the Pagenstecher operation; but on referring to the original author and in correspondence with German writers I now fully agree with Elschnig (editor of Czermak's *Augenärztlichen Operationen*) in his letter to me of Feb. 1, 1909, in which he says: "Pagenstecher's operation is quite the same as Smith's."

Pagenstecher seems to have been the first to express the lens by external pressure (1871[1]) and Terson (1872[15]) and Wolkow (1894[16]) next report such procedure. Smith does not write until 1900.[9] Pagenstecher used his spoon to press the posterior lip of the wound back and to slide the lens thereupon. Smith[9] now passes the spoon behind the edge of the lens to assist its birth or extrusion, passing it into the vitreous on occasion of a hard delivery. So did A. and H. Pagenstecher and so did all of us.

The modifications of the Pagenstecher operation have varied from bizarre changes in place of section (Macnamara, outward, 1871[17]), introduction of spoon, hook

or loop (Caspar, 1878[18] Higgens 1888[19]), tearing of zonula (Andrew, 1883[8]), dislocation of lens into anterior chamber by sclerotic puncture, Canstatt (1870[20]), Roosa (1885[7]) tore the zonule by partly dislocating the lens with the Graefe knife, Gradenigo (1895[4]) used a zonulotome, Wolkow (1894[16]) used two spoons for pressure and counter-pressure, etc. Mulroney, at Amritsar, India, began in 1890 to make a downward section without iridectomy, and this procedure has been adopted by Smith[9] (with upward corneal section), "who now has many imitators."[12]

We will now take up the operation itself according to my experience, leaving other phases and details to our confrère, Dr. Greene.

I do not deem the purely corneal section acceptable, for this is followed by slow healing, iridic prolapse (Herbert[12]), distorted pupils (Greene, 1906[14]) and excessive astigmatism, neither is the operation without iridectomy, on account of iridic prolapse. My experience has shown the 2/5 sclerocorneal section with conjunctival flap, as where this is made delayed union is unknown (Maynard[11]), combined with a very small iridectomy and extraction of the lens, *i. e.*, the regular operation less a capsulotomy, in immature and hypermature cataracts, is the only all-round satisfactory operation. The ordinary run of mature cataracts may be as well operated on with less risk in the average hands by the generally adopted combined flap extraction with capsulotomy; cataract in children and traumatic cataracts by discission.

The "absence of details," *i. e.*, the least handling of the eye and the fewest instruments possible, is the characteristic of this operation and what with the *tactus eruditus* makes it successful in the hands of Smith, Greene and others; while in some other hands—notably the critics of the method—especially those of India—"do not appear to have benefited much, judging from their results."[12] It is no operation for a beginner, neither is it for the average operator.

A stop speculum should not be used on account of the ever-present danger of vitreal prolapse. The lifting of the upper lid by a squint hook seems crude. I use the lidholder of William Fisher, of Chicago, and have the patient's upper lid—the only one of moment—under full control, and thus lose vitreous in not more than 5 per cent. of cases either with or without capsulotomy. The eye is fixed by catch forceps, the knife is entered (the only instrument entering the eye), and a corneoscleral section with a conjunctival flap is made. A very small iridectomy is made, the section of the iris only embracing the pupillary margin and edge of the sphincter muscle, by pressing the ends of iris forceps on the cornea over the upper part of the pupil, when the iris will usually prolapse, the edge being seized by the forceps, the iridectomy is completed by a single cut of the scissors. The bend of a large hook is then pressed moderately, slowly and continuously on the cornea at the lower edge of the lens, that tilted backward, the pressure gradually relaxing as the upper edge of the lens enters the wound, the body of the lens is lifted up by the pressure of the hook, which follows it in its delivery; the flat spoon of Pagenstecher or Smith may be used to assist the lens to slide out of the eye by offering an inclined and smooth plane for it to glide on. Seldom is the spoon entered into the eyeball; forceps are occasionally necessary to seize the lens when impacted between the lips of the wound; and the act is completed by the crochet end of the hook catching the lens, on its delivery, rotating it out of the wound, the conjunctival flap and the iris stroked back into place, the lids closed and a light bandage applied. This is a brief description of the method I have adopted and adapted. My expression cases are comparatively few, but compare very favorably, and in fact the results are to my mind better than those of about 1,000 regular extractions performed by me within the last twenty years.

My cases, grouped under dates of the expression operations, are as follows:

CASE 1.—Oct. 3, 1904: Mrs. S., aged 58. Immature cataracts R. & L. Preliminary iridectomy and direct trituration with Boettmann's spoon by me October, 1903, on L. E.; no ripening. Extraction of cataract with aid of Pagenstecher's spoon which entered the eye, no loss of vitreous. V. + 9.00 ⊃ 1.00, 180° = 6/vi.

CASE 2.—Oct. 15, 1905: Same as Case 1. I had done preliminary iridectomy without trituration on this eye in October, 1903. Normal expression operation on mature cataract of R. E. V. + 9.00 ⊃ + 1.50, 165° = 6/vi.

CASE 3.—March 12, 1906: Mr. F. D., aged 65. R. immature, L. mature. Small iridectomy, normal expression in capsule of L. V. + 12.00 ⊃ + 2.00, 90° = 6/xii. See also (12).

CASE 4.—March 9, 1907: Mrs. Z., aged 61. Hypermature black cataract, small iridectomy, expression with slight loss of vitreous, corneoconjunctival stitch after. V. + 10.00 ⊃ + 3.00, 180° = 6/xxiv.

CASE 5.—March 18, 1907: Mrs. S., aged 59. Mature cataract, small iridectomy normal expression. V. + 10.00 = 6/xii.

CASE 6.—March 23, 1907: Mrs. E. J. J., aged 60. Mature black cataract, small iridectomy, expression normal until lens was pinched in wound when a portion of the anterior capsule tore off, sticking in wound, removed by forceps without entering the eye, a slight iritis developed; the hyaloid membrane apparently participating in the opacifying process, as several months afterward a fine membranous opacity was observable on focal illumination. I have not seen this occurrence before or since. V. + 10.00 ⊃ + 150, 15° = 6/vi; but on development of the hyaloid opacity was reduced to 6/viii with correction.

CASE 7.—April 10, 1907: C. C., aged 48. Mature cataract, small iridectomy, normal expression. V. 10 days later with 10.00 about 6/xxiv. I did not have the opportunity of prescribing lenses or observing the vision later as he did not return after leaving the hospital.

CASE 8.—June 19, 1907: B. O., aged 65. Mature cataract, normal expression except capsule ruptured, lens removed by sliding on spoon and capsule pulled out of wound with forceps without entering the eye. V. + 10.00 ⊃ + 2.50, 180° 6/viii.

CASE 9.—Nov. 6, 1907: R. W., aged 45. Immature cataracts, small iridectomy, normal expression, corneal incision (the typical Indian operation), very slow healing of wound, iritis, four weeks in hospital. High astigmia followed, although visual acuity was very good. V. + 11.00 ⊃ + 4.00, 135° = 6/xviii.

CASE 10.—Nov. 11, 1907: Mrs. A. S. Hypermature cataracts with tremulous irides and synchysis vitrei. There being fair perception and iris reaction in the left, I attempted ordinary combined extraction, corneoconjunctival stitch (Kalt) placed before incision, but lens popped out in the capsule with considerable loss of vitreous. Result for a few months was V. = movements of hands and large objects. Further degeneration set in so that in May, 1908, eye was blind. (See Case 19).

CASE 11.—Nov. 12, 1907: Mrs. S., aged 70. Hypermature cataract, small iridectomy, capsule ruptured and was not entirely removed from eye on account of rupture of hyaloid with slight loss of vitreous, caused by attempt at removal by iris forceps entering the eye, conjunctival stitch. Four weeks in hospital with iritis. V. two months afterwards + 12.00 = 6/xxxvi.

[20] Canstatt: Briefl. Mitteilung betreffend eine neue Idee sur operative Heilung des grauen Staars, Klin. Monatsbl. f. Augenh., 1870, pp. 131-133.

Case 12.—Dec. 13, 1907: Patient in Case 3 returned on account of satisfactory result on L. E.; V. then being 6/viii with old correction, increased to 6/vi + 2 with decreased cylinder. Normal expression, immature cataract, small iridectomy. V. + 12.00 ⊃ + 1.00, 90° = 6/viii.

Case 13.—Jan. 6, 1908: C. C., aged 40. Morgagnian cataract, normal expression, small iridectomy, lens aided in delivery by forceps as it became impacted into wound, no entrance of forceps. V. good. Refraction not recorded.

Case 14.—Jan. 29, 1908: C. W., aged 69. Immature cataracts both eyes. V. 6/lx and 3/lx. L. E., corneal incision, small iridectomy, normal expression except that lens came out very slowly and seemingly took considerable pressure in delivery. Striped keratitis for two weeks. Very high immediate corneal astigmia (6.00, 180°). V. + 11.00 ⊃ + 5.50, 180° = 6/xxxvi. Astigmia reduced in May, 1908, to 3.00, 180°.

Case 15.—Feb. 21, 1908: E. B., aged 58. Immature cataract, rather large iridectomy, expression followed by small bead of vitreous, conjunctival stitch. V. + 10.00 = 6/xii.

Case 16.—March 21, 1908: O. P. H., aged 75. Robust health, two years blind with mature cataracts. R. E. chronic conjunctivitis and dacryocystitis. L. E. apparently normal, no pus germs on microscopic examination, three days' bichlorid of mercury treatment to eye and Seiler's solution in nose. Small iridectomy normal expression, brown cataract. Corneal astigmia 1.50, 180° V. + 10.00 = 6/xxiv. Increased in May, 1908, to + 11.00 = 6/xii. (See Case 18).

Case 17.—May 5, 1908: Mrs. S., aged 64. Mature cataract, normal expression with rather large and uneven iridectomy. V. + 11.00 ⊃ + 1.50, 15° = 6/viii.

Case 18.—May 21, 1908: Patient in Case 16. April 1, 1908, I excised the lacrimal sac according to Meller's[21] method securing union by first intention and kept him under antiseptic treatment with bichlorid of mercury solutions locally until May 22, 1908, when I made normal expression of the right cataract with small iridectomy. V. + 10.00 = 6/xxiv.

Case 19.—May 21, 1908: Patient 10 returned with L. E. blind from degeneration, and as a last resort I made expressive operation on the R. E., which only had poor perception and projection, Morgagnian cataract, synchysis vitrei, having no complications and to my surprise getting 6/lx vision with + 10.00, but a few months later vision further deteriorated and the end results are unknown.

Case 20.—June 5, 1908: Mr. S., aged 43. Morgagnian cataract, normal expression, small iridectomy. V. + 10.00 = 6/lx.

Case 21.—June 19, 1908: Mrs. H. W., aged 61. R. mature L. immature cataracts, normal expression with small iridectomy R. except that capsule ruptured within the eye and some remained. Opacity cleared up under dionin. V. + 11.00 = 6/xxiv. (See also Case 28.)

Case 22.—June 20, 1908: Mrs. M., aged 60. R. E. blind from previous iridocyclitis following attempted extraction of cataract by another operator. L. E. poor perception and projection. L. E. Morgagnian cataract expressed aided by forceps which entered the eye, much loss of fluid vitreous. Cataract with black nucleus. No result as eye went on to iridocyclitis.

Case 23.—July 16, 1908: M. O., aged 63. Immature cataract, expression with small iridectomy, capsule ruptured before delivery, extracted with forceps entering the anterior chamber, small bead of vitreous extruded and was cut off, conjunctival stitch. V. + 10.00 ⊃ + 1.75, 180° = 6/viii.

Case 24.—July 21, 1908: N. O., aged 69, had an attempted extraction done by another surgeon in L. E. with result of incarceration of iris and partially dislocated immature cataractous lens with resultant vision of fingers at 2.00 M. As the vision of the R. E. was less than the L. E. through the lenticular opacity I attempted expression with iridectomy, but the capsule ruptured and vitreous escaped, necessitating entrance of the spoon and delivery of the lens, conjunctival stitch. Patient had postoperative mania occasioned by fear of not regaining vision, owing to his previous experience and from the fact that his brother was totally blind after an unsuccessful cataract operation by the same operator on his only remaining eye, the other being injured and blinded by an accident. Nov. 6, 1908, I made a discission of pupillary membranes securing a clear pupil with normal looking fundus; but patient declared and persisted in the statement that he could not see, becoming very childish, so he was taken home and the end-results are unknown to me.

Case 25.—July 30, 1908: Patient in Case 23 returned and I made normal expression of immature cataract with small iridectomy on left eye. V. + 10.00 ⊃ + 2.00, 180° = 6/vi.

Case 26.—Aug. 3, 1908: Mrs. M. S., aged 51. Immature cataract, normal expression with small iridectomy. V. + 10.00 ⊃ + 1.00, 180° = 6/xxx. As the other eye has yet good sight she prefers to go without this correction.

Case 27.—Aug. 6, 1908: Mr. F., aged 54. Immature cataract, normal expression with small iridectomy. V. + 12.00 ⊃ + 2.00, 15° = 6/xxxvi.

Case 28.—Sept. 2, 1908: Patient in Case 21. Expression L. with small iridectomy; fluid vitreous escaped, spoon entered eye, conjunctival stitch, hyphema, dionin. Oct. 22, 1908, discission. V. + 12.00 = 6/xxiv.

Case 29.—Sept. 18, 1908: J. R. W., aged 80. Mature cataract both eyes, very smooth normal expression with small iridectomy R. E. Clear black pupil and counting of fingers immediately after operation. Very nervous patient; two days later had postoperative mania, got his fingers under the bandage despite attention of special nurse, infected eye which was lost through panophthalmitis.

Cases 30 and 31.—Nov. 21, 1908: H. B., aged 57. Five years before this date I had extracted an immature cataract from his right eye, finding the zonula weak; the lens came out with the capsule. V. + 10.00 = 6/vi. Nov. 10, 1908, I attempted operation, but on completing sclerocorneal incision found that a bead of vitreous protruded into the anterior chamber, closed up the eye and November 21 made new incision with iridectomy; perfectly normal expression. V. + 10.00 ⊃ + 1.00, 180° = 6/viii.

Cases 32 to 37.—In addition to the above I have made six expression operations at my public clinic, the case histories of which are not complete nor at present accessible. In one of them there was loss of vitreous, in two rupture of the capsule but all recovered with useful vision.

I append three more recent case histories which apply to this subject, although they can not be classed as expression operations, in two of them the lens being removed in its capsule by the aid of the wire loop, in one of which detachment of the retina followed later, and in the other owing to the corneal incision a high degree of astigmia with delayed union followed the operation. In the other the interest centers on the failure of expression, followed later by successful combined extraction.

Case 38.—May, 1897: J. M. C., aged 50. A diabetic and myope of — 4.00 D. submitted to a flap extraction by me in the right eye. On account of rupture of the zonule and loss of vitreous I removed the lens by the wire loop, ten days later, V. with + 8.00 = 6/vii. Gradual loss of sight followed, and when seen a year later detachment of the retina and optic nerve atrophy was found.

Case 39.—May 2, 1908: Patient in Case 38. I made typical flap extraction with iridectomy on the left eye after attempting expression but had to do a cystotomy; the lens capsule, however, was extracted with forceps. V. + 10.00 ⊃ + 2.00, 90° = 6/xxiv.

Case 40.—September, 1908: I operated at a clinic on a man of about 60 in whom an attempt by another operator at extraction of cataract had been made but the lens had not been removed. Here I found a cataract with posterior synechiæ. Ordinary attempts at extraction of the lens after the incision

* 1 ultimate detached retina.

of the sclerocornea without conjunctival flap failing to deliver I passed the wire loop behind the lens and delivered it without loss of vitreous. I understand on good authority that there was slow healing of the wound which possibly may have reopened and the lips of the wound overriding each other being followed by a very high degree of astigmatism 6.00 or 8.00 D. I have, however, not had the opportunity to examine the case since the day of operation.

I am convinced that from the circumstances under which the Indian operators are placed, the apparent lessened susceptibility to infection of their patients, the fact that wounds on Hindoos, like those on the lower races and wild animals, are more prone to heal than in the cultivated classes, and, above all, that these patients disappear from observation soon after the operation, we must depend for the end results on the testimony of others who practice in more civilized countries, where the patient's life history can be followed with more exactions. Therefore, the reports of Cheney,[13] Greene and others, although in proportion showing such a paucity of patients, are of more value to us.

"If the dread of the remote complications is relieved by further experience there is much to be said for the operation" (Elliot[22]). If the ultimate results of the operation are good in the foregoing cases I shall continue to practice it in selected cases.

The operation is not one to be attempted by any but the most skilled operator, and even with him is not to be chosen as a routine method, for it is a far more dangerous operation, except in the hands of an operator whose touch is fine, who has no trembling fingers and whose judgment is the most exact.

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. WÜRDEMANN AND GREENE

Dr. Peter A. Callan, New York: I have never done this operation in uncomplicated cataracts. I have done it with a great deal of comfort to the patient in cases of dislocated lenses, and know of no operation that affords such good results when the lens is dislocated into the vitreous, and when, if proper pressure is made, the lens appears at the lips of the wound and emerges without loss of vitreous. I have been satisfied with the old operation, even if I have to make a secondary operation, and I think the dangers of a secondary operation are all due to choice of method in operating. I have seen Major Smith operate and it appeared to me that it was a contest between how much pressure he would apply and how much the hyaloid membrane would stand; in other words, a great amount of traumatism was required to expel the lens in its capsule, and we all, theoretically, at least, know that the more an operation is accompanied by traumatism the more likely the eye is to become inflamed from germs and infection, or iritis and iridocyclitis result, not to speak of loss of vitreous. There is usually no occasion, or rarely, at least, in the old operation to lose vitreous if the patient behaves himself. I have no doubt that this operation affords a great many possible points of advantage to Dr. Smith. He is a ruler, you might say, of an immense district. These patients come to him, he sees them for about one week, and then they disappear, never to be seen again. They are peasants. They are a class of people who do not demand much. They do not read, they do not write, they are living the simple life close to nature, and I think their eyes will stand a great deal more than our workers in the city would stand. Possibly I have no right to criticise this operation, inasmuch as I have never tried it, but I have been afraid to try it. I did not feel that I had any right to try it, as the methods ordinarily used gave me such good results. I hope that inexperienced men who have not the facility to gain experience will not rush in owing to the success of Dr. Greene and Würdemann, and of Major Smith, who is in a class by himself—a man who might perhaps take any kind of a knife and perform a cataract extraction with possibly perfect safety. It makes all the difference in the world whether one has that wonderful technic that he has. I do not think it is fair to put ourselves in that class. It seems to me that until we become practically perfect we ought to stick to the methods we are accustomed to and in which we are proficient.

Dr. Arnold Knapp, New York: I am very sorry that I can add very little on the subject of extraction in the capsule to what is contained in my description of a visit to Major Smith which was published in the *Archives of Ophthalmology* last year. I should like to say that in my opinion Major Smith's statistics are accurate. The operation is undoubtedly much more difficult than the ordinary one. Its value can only be established by exact statistics on the visual results obtained and by a record of the subsequent life of the eyes which have been operated on after this method. There can be no question but that the loss of vitreous even with the most skillful operators is much greater than in the ordinary operation. Loss of vitreous, to my mind, may mean imperfect healing of the corneal wound, entanglement of the iris, and subsequently a peculiar transformation of the anterior layers of the vitreous into slightly opaque tissue which interferes with vision. Even if the cataract is successfully removed in the capsule, reposition of the iris, straightening out of the columns of the coloboma can not be practiced with any degree of freedom for fear of vitreous prolapse, which is especially apt to occur at the end of the operation; consequently peripheric iritic adhesions or moderate prolapse of the iris were the rule in the cases which I observed. On the other hand, extraction in the capsule is an ideal and beautiful operation when the dislocation of the lens takes place readily. There is no postoperative irritation or inflammation of the iris and no further trouble with the capsule, which in many cases makes the secondary operation more hazardous and difficult than the first. The Indian patients, though younger in years, are about as old as ours, as they mature and grow old earlier. They are usually emaciated and very thin. I did not observe in India any of the fat, plethoric patients who with us are so notoriously prone to postoperative complications. The cataract patient in Jullunder is subjected to practically no preparation and is operated on directly after admission. Perhaps on the whole they are better behaved during the operation. Through the courtesy of Dr. Greene I was able to compare the lenses which he had extracted in the capsule in this country with some that I had brought from India. There was no appreciable difference. I wish to express my admiration for Dr. Greene's excellent results and trust that observation of the subsequent course of these eyes may confirm the claims which have been made for this operation.

Dr. Casey Wood, Chicago: Recently, at the invitation of Dr. D. W. Greene and in the company of Dr. Edward Jackson, I spent two days of about ten hours each in examining patients, witnessing and assisting at the procedure commonly known as Major Smith's operation for cataract. This work, done by Dr. Jackson and myself at St. Elizabeth's Hospital, the Old Soldiers' Home, and in Dr. Greene's private office, included a careful examination with the oblique illumination, the ophthalmoscope, and other methods of precision of patients who had been previously operated on (many of them reported) by this so-called Indian method and in comparing them—especially in the Soldiers' Home—with extractions done at various dates by other methods. In this way I had an excellent opportunity of watching the steps of the Smith operation as performed by Drs. Greene and Bonner in nine cases and of critically reviewing the results of the operation in the persons of 47 other patients who had submitted at the hands of Drs. Greene, Bonner and Millette to the Indian form of extraction from a few days to three or more years previously.

Of the 47 patients examined by the ophthalmoscope, etc., I never saw a single case of glaucoma or detached retina, although Greene, in his paper, reports one or more of the former.

The proportion of unusually good vision (20/15 to 20/30) was, I believe, greater than results from ordinary methods of extraction. I not only found central vision in those cases already reported by Dr. Greene to have been correctly reported but in some six instances to have been better than that set forth in his reports. This is a circumstance that lends plausibility to the claim that, while eyesight tends to deteriorate (chiefly as a result of opacification of the capsule) during the first six months following the older methods, it improves after the Smith operation, owing to the absorption of intraocular bleeding and the re-establishment of normal vascular conditions disturbed by corneal and other traumatism.

---

[22] Elliot: Cataract Extraction, Brit. Med. Jour., Dec. 19, 1908.

The eyes operated on showed very few traces of iridic, capsular, hyaloid or pigmentary incarceration; the sclerocorneal wound appeared to have healed as smoothly as in the older forms of operation, and, with few exceptions, by first intention. The media were found to be exceptionally clear and the black, generally large pupil give an unobstructed and well-defined view of the fundus.

On the other hand, patients recently operated on showed, in practically every instance, decided scleral and faint ciliary injection—a vascular engorgement that appeared to me to persist longer than after the classic modes of extraction and to be due to mechanical irritation—traumatism involving the cornea, iris and, possibly, the ciliary body.

Corneal alterations—haze of the *substantia propria*, disturbances of the anterior epithelium, mild forms of keratitis—I saw in several cases of recent extraction; but I do not think that striped keratitis or other forms of the more serious corneal changes were seen more frequently than in the older operations. Properly or not, I regarded these early keratitic sequels as due to the friction of the cornea by the end of the strabismus hook.

Although there were no cases of thickened capsule or of capsular remains (except in a few instances in which the latter had ruptured during the operation but did not obstruct central vision), yet I saw seven instances of decided exudation into the posterior chamber, two evidently vitreous hemorrhages, five of them deposits on the hyaloid membrane.

There were many small, ideally shaped, key-hole pupils, but more than a majority were wide and large, with a tendency to upward displacement—a condition that, of course, marred the cosmetic result, even though it did not interfere with central vision at the near point.

If from this slight experience I might be allowed to venture an opinion as to the place of the Smith operation in ophthalmic surgery, I would say that, given an experienced, intelligent and skillful operator, working in conjunction with a tried and equally experienced assistant and counting success in cataract extraction entirely from the standpoint of the amount, quality and persistence of central sight six months after the operation, the Major Smith procedure is the best method for extracting all forms of senile cataract with which I am acquainted.

Dr. Walter R. Parker, Detroit: I have attempted the extraction of the lens in the capsule in 23 cases. In 3 of the cases I failed. One patient had postoperative mania the night of the operation and the eye was lost through panophthalmitis. This leaves 19 results about which to speak. In the 19 cases the average of vision from 10 days to two weeks after the operation was 6/36, not quite so good as the average of vision in the patients operated on by the regular method. In about 50 per cent. of the cases the lens turned on itself and was delivered in the classical way. The other 50 per cent. presented the upper edge first. There was a slight loss of vitreous in 21 per cent. of the cases. In no case was there any iritis, and in no case was the loss of vitreous so large that it influenced the result in any way. That the operation is a difficult one I think can not be denied. It certainly is more difficult than the classical operation. I have done about 480 extractions, 23 of them being those I have mentioned by this method. The first case I had was simplicity itself. The lens, presented with its upper border, came out very easily, and in that case before the patient left the hospital he had vision 20/20. That is the only case in which I can report the ultimate result. It was reported in the *Ophthalmic Record*, April, 1906. The amount of keratitis is much greater by this method than by the regular method. Dr. Greene has cleared up a point that in the few cases I have done has bothered me very much. If you will examine the eye carefully after operation you will find corrugations running vertically. This condition Dr. Greene attributes to disturbance in the anterior vitreous. That a trained assistant is necessary seems to me certain. The operation has been simplified very much in my hands by the new instruments, the large hooks and the double spatula. I think if one reads the original description by Major Smith one is inclined to believe there must be prolonged constant pressure on the cornea. After the pressure on the lower part of the cornea has ruptured the capsular attachments below, then all the pressure is stopped so that the lens will have an opportunity to come anteriorly, and it can be turned on itself by manipulation.

Dr. W. H. Wilder, Chicago: I think that in arriving at a conclusion on any important procedure which is more or less of an innovation we must study and analyze very carefully the results of any series of cases. Not wishing to offer any captious criticism of these papers, I should like to call attention to the fact that the first essayist whose paper purports to be a record of 40 cases of extraction in the capsule includes 3 extracted with the wire loop when he feared the vitreous might escape, an operation we all do in an emergency. Furthermore, there is no detailed record of the 6 cases from 32 to 37, so it is impossible to see how they can throw any light on the value of the operation.

The first essayist further advises that this operation be performed only in selected cases and "is not one to be attempted by any but the most skilled operator." This is conceded by all, and we must look to these skillful operators to guide us in this new operation.

Major Smith, I think, confesses to a loss of vitreous in from 7 to 8 per cent. of his cases, but the first essayist shows unquestionable skill, for he claims a loss of no more than 5 per cent. Referring to the value of the lid holder in place of the squint hook of Smith, he states that he loses "vitreous in not more than 5 per cent. of cases either with or without capsulotomy." The analysis of his cases, however, tells a different tale.

I do not wish to criticise his results in the least; he must have a great deal of skill, for he has had the opportunity, as he states of operating on 174 cases of cataract in the last two years, else how could his records show 37 of his 40 reported cases done since March, 1907, "selected" and suitable for this operation. I only submit that in offering conclusions to the profession, as guides to practice, one should show extreme care, not only as to statistics, but also as to the degree of enthusiasm manifested for the new method.

The first essayist states in his abstract that he finds this intracapsular operation as successful in his hands as the ordinary method of extraction; another evidence of his great skill, but not a very safe guide for the rest of us.

I have seen a number of these operations done by Dr. Greene at the Illinois Eye and Ear Infirmary, where I have many cases, but unfortunately not so many as 174 in two years, but have not felt it wise to vary from the old method. But I do see, if this can be proved successful in immature cataracts, it will be an extremely valuable method. Dr. Greene kindly consented to do some operations in our clinic and I had the pleasure and profit of assisting him. I wish to compliment him on the way he did them. Of the patients operated on 3 were mine. One patient with Morgagnian cataract got along beautifully. There was violent reaction after several of the operations, and in many of the patients there appeared this latticework keratitis which usually, I understand, clears up, and in most cases did, but not in all. One patient left the house with an opacity of the cornea which might be due to an injury to the membrane of Descemet. But, until we get some more positive statistics than those of Major Smith, the character and temperament of whose patients are so different from ours, we should withhold judgment; and then we should demand that such statistics as are presented to us be reliable in all details, because if we are going to weigh successfully the value of this operation we must know how much loss of vitreous occurs, what vision we get, and whether the after-history of the cases is as favorable as with the old method.

Dr. Percy Fridenberg, New York: It may be of interest to those present to hear of the after-history of the operations done by Major Smith at the New York Eye and Ear Infirmary last summer in the clinic of Dr. Gruening, then under my charge. One patient had had a preliminary iridectomy two weeks beforehand. The operation itself was performed without complications whatsoever, and that the assistant was sufficiently trained may be known from the fact that it was Dr. Arnold Knapp. The thing noticed by all the observers near was that both of these patients complained of intense pain. The second point was that the expression of the lens seemed to take much more time than usual. Dr. Callan has called attention to the fact that it is attended with a great deal of traumatism. When the patients' eyes were bandaged and they were sent back to the wards I asked Major Smith when he wanted them dressed. He said "Let them go four or five days; there are no complications to be feared and there is no necessity for an early dressing." Our practice is to redress them 24 hours after the operation. Acting on his instructions we let them go an extra day. In both cases there was an extreme reaction. In both cases there was very marked striated keratitis. In the case in which the iridectomy had been performed combined with the operation a narrow iridectomy without reposition of the coloboma but immediate expression of the lens, there was very marked iritis which progressed in spite of careful treatment. I had Dr. Gruening come down and see the case. It went from bad to worse and was one of those sluggish cases of iridocyclitis, and at the end of a month vision was practically *nil*. In the other case there was a severe striped keratitis, which gradually cleared up, but on the third day the patient, a woman of 63, complained of a great deal of pain in the eye and herpes of the cornea was found. I do not know whether the traumatism produced that or not, but it cleared up and finally the sight was 20/50 with correction.

Dr. L. Webster Fox, Philadelphia: Two years ago at our Symposium on Cataract before this Section I had assigned to me "The Delivery of the Lens and the Toilet of the Wound." Up to that date and since I made many attempts to deliver the lens in its capsule, after the method of Pagenstecher, and later, following as nearly as I could the Smith method, even going so far as to devise various shaped instruments to assist in the delivery of the lens. As I was searching through the literature I found that Dr. Greene had written the best description on the subject, and that his experience with the operation exceeded that of any other surgeon in our country. Having these facts in hand, I communicated with him. Later he invited me to Dayton to witness eight operations by the Smith method. Having become encouraged by the ease with which Dr. Greene delivered these cataracts in their capsules, I have, since my return home, performed five operations by that method. The first three were ideal; the fourth was performed on an unruly patient, and, while the lens was delivered, yet considerable vitreous was lost; the fifth was similar to the fourth, only the loss of the vitreous was greater and the result was a collapsed eyeball. [illegible] fact that I filled the eyeball with normal [illegible] was no vision in the eye, although the rotundity of the globe was restored—there evidently was complete separation of the retina. Dr. Greene is right when he asks: Is this operation to take the place of our common practice, or is it too difficult for the average ophthalmic surgeon to follow, or can it only be followed by the most skilled operators. Let the question be settled by those having exceptional opportunities? At present I am non-committal, but intend to follow this method until I have acquired more dexterity than I possess at present. I endorse Dr. Callan's advice that it is not fair to his cataract patient for any surgeon to operate by a new method until he has mastered the technic of that operation on pigs' eyes. I am sure that it is a practice which may well be adopted by all ophthalmic surgeons. This country must decide whether this operation is to be a popular one or not. From what I can learn the ophthalmic surgeons of European countries are not enamored with it, so far they have fixed our methods.

Dr. Frank Allport, Chicago: The first question that I wish to solve is: Am I going to give up an operation with which I am familiar and feel competent to perform and one which yields me excellent results, for one with which I am unfamiliar and one requiring extra skill and much experience to perform satisfactorily? In other words: Which operation in my hands will perform the greatest amount of good to the greatest number of people? The Major Smith operation is undoubtedly an excellent one and frequently yields startlingly brilliant results. In Major Smith's hands, with his constant practice and enormous experience, he is doubtless justified in the continuance of its performance. Dr. Greene, with his large operative material and natural and acquired operative skill, is doubtless justified in this work. I would be glad to trust my own eye in the hands of either of these gentlemen. The questions for me to settle, however, are: Am I going to experiment with this operation? Am I justified with the limited number of cases which I have at my command *per annum* in abandoning a satisfactory procedure for an extra hazardous operation with which I am unfamiliar and which requires an extra amount of skill to perform? I imagine this is a problem which we will all have to solve and I hope it will be solved in a manner which will best subserve the interests of our patients. I am an average operator with an average practice and with an average amount of skill. My senile cataract cases, I am sure, do not exceed 25 a year, and I do not consider that this number justifies me in experimenting with the Smith operation. Does it justify most of the gentlemen here present? I was particularly impressed with one thing that Dr. Greene said, namely, that it seems to be essential to success that the patient must constantly look upward in order to do away with the traction on the part of the inferior rectus muscle. This seems to me to be a great objection to the operation because it is practically impossible always to control the voluntary action of the eye on the part of the patient.

Dr. M. Wiener, St. Louis: I was one of the early enthusiasts regarding this operation. I have attempted 42 extractions in the capsule, 2 of which ruptured and can not be counted; I have had 7 vitreous losses. I abandoned this operation nearly two years ago and I will not perform another for a long while. I have had 3 cases of these 40 patients return with a membrane across the pupil. In 2 of these cases there was no loss of vitreous. One of them occurred a little over two years after the operation. Now if a membrane is going to occur where the capsule is removed I can not see the advantage of it, especially when the operation is very much more difficult than the usual extraction with iridectomy. Another danger which might be mentioned is this: I lost only one eye and that was in a case in which the operation itself was everything that could be asked; the lens rotated properly; but on the third day after the operation the patient developed a cold. He coughed and suddenly complained of pain in his eye. On removing the bandage I found a large bead of vitreous in the wound which I clipped off, but the eye atrophied and no vision was obtained. Of course, this might also happen when the posterior capsule remained intact, but it is not nearly so liable to happen. I think we should hear more of the ultimate results of this operation before proceeding too rapidly.

Dr. Mark D. Stevenson, Akron, Ohio: I have attempted the operation in 14 cases. In 2 I failed by rupturing the capsule. I had 2 losses of vitreous and 1 severe iritis. Every patient has good vision so far. I learned much concerning this operation during some visits I made to Dr. Greene last summer. I wish to emphasize the importance of a large corneal incision—fully the upper half. I do not especially like a conjunctival flap in this operation, especially toward the sides. A small one at the summit of the corneal flap may cause no trouble and be useful. I do not make a wide iridectomy but simply cut the iris through the sphincter, not removing any of the iris. After making the corneal incision and performing an iridectomy I stand at the side of the patient and the assistant stands at the head. By removing the capsule with the lens, there is not only no necessity for future needling, but the troublesome capsular fragments which in other operations lie in the wound, preventing healing, causing iritis, etc., are not present. There is no swollen ring of cortex as in other operations pressing against the iris. At a meeting of the Ohio State Medical Association last month I first heard Dr. Greene state that the lens often turned over in its exit from the eye. Months before and the first time it occurred to me I thought it was an accident, but it was such a successful operation without loss of any vitreous, that I decided in the future to try to make the lens turn over. First I rub the cornea with the end of the hook a little above the lower border and parallel to it, gradually widening my arc until the lower part of the zonula is considerably depressed. Next I rub on the margin of the cornea and even on the sclera pushing it behind the edge of the lens which has been displaced not only backward, but because of its slanting surface, upward. As soon as the lower edge of the lens is in front of the crease pressed into the cornea by the hook, the hook is gradually swept upward and the lens inverted with much less chance of vitreous loss than if it had been pushed directly out of the eye. In this way, the lens comes first and the corneal opening is blocked until it passes. I have found that a properly shaped Pagenstecher's smooth glass rod spatula makes an excellent instrument with which to press the cornea. I think I prefer it to the strabismus hook. I would not advise the use of forceps in delivering the lens, as the capsule would immediately rupture.

Dr. J. W. Millette, Dayton, Ohio: I have assisted in a goodly proportion of these 75 cases and have carefully followed the development of each case and have correlated and prepared the statistics in connection with the paper, and I desire to state that Dr. Greene has approached this work in the true spirit of the student. Recognizing the imperfect character of cataract work, and trying to find some better method, he has given us the truthful record of the results obtained. He requested that I speak briefly of what the assistant does. During the incision and iridectomy the upper lid is retracted by the Noyes elevator. The lower lid is slightly retracted with the face of the thumb or index finger. I most frequently use the finger. The patient's lids are under absolute control, a thing that is not true and can not be true with any speculum with which I am acquainted. The patient can not do harm by squeezing. From the time the incision is finished the patient may do great harm by contraction of the inferior rectus, which opens the flap and exposes the contents. If he will persistently look toward the ceiling, as he lies on his back, he is in as nearly perfect condition as is possible. After the iridectomy is made I lay aside the Noyes elevator and use the large hook. With this the action of the orbicularis is under perfect control.

The operation has some features which will hinder its universal adoption. 1. It requires a trained assistant. Major Smith and many of his followers say that the assistant is almost as important as the operator himself. 2. It requires a greater degree of skill than the capsulotomy method. Sufficient skill may be attained by any man who has skill enough to do the ordinary extraction, if he will practice. I do not advise practice on pigs' eyes, nor calves' eyes, nor sheep's eyes. I have wasted dozens of them. They are most unsatisfactory. But a good live dog, properly bound up, is a good subject. Rabbits are good, the dog is the best in my experience. 3. There is a somewhat greater degree of violence than in the other methods, but the violence to the cornea even is not so great as it seems. I have observed that the men who have been in these clinics and have placed the hook on the cornea have been prone to begin with too much force. A little more force than the weight of the hook is sufficient, together with the pressure in one place with the spud. 4. There is also loss of vitreous more frequently. As to the future of the eye from loss of vitreous, up to one-third, we have no positive statistics. We should hold ourselves agnostic. There may or may not be future evils resulting from this minor loss. 5. The cosmetic effect is not so good, but occasionally we do get that ideal keyhole appearance. Ordinarily the pupil is "U"-shaped with a broad base and frequently displaced upward. However, I believe that there are four considerations to which we must give their deserved supremacy. The first is the permanent disposition of the capsule and its contents. Second, a secondary operation is avoided. Third, postoperative complications are practically *nil.* Fourth, most important of all, we get better vision.

I have had the privilege of studying the 75 operations by the capsulotomy method just preceding these. As nearly the same kind of eyes as one could get, patients of the same character, the same age, operated on by the same operator under conditions as nearly identical as could be, and the vision, as recorded in these records, with the capsulotomy method was 20/40, while with the Smith method it is 20/27. But to know more fully the good and bad qualities of the method and to know if it be generally practicable, we must have the results of more operators carefully and without prejudice recorded. The pioneer work being done in the clinics at St. Elizabeth's Hospital and the National Military Home at Dayton should be emulated. We want to know the best, for the best will never reach the conscientious oculist's ideal for his patient.

Dr. H. V. Würdemann, Seattle: As is to be expected, the sentiment of the Section is somewhat unfavorable from the theoretical side, but, gentlemen, try 10 operations and then come and talk about it. In pushing the lens back I do not think when it turns it goes into the vitreous through the fossa patellaris, through the hyaloid membrane; in the cases in which it makes the characteristic somersault I have not lost vitreous. In the others in which the whole ligament seemed to rupture and the lens came straight out I have had loss of vitreous probably most of the time. There are less postoperative disturbances. I have practically no iritis, 0.5 per cent.—see the statistics of Smith, those of Dr. Greene and my own. Iritis may be due to infection. In some of my early cases I failed to deliver the lens and I went on with the other operation. The central acuity seems to improve after the operation rather than to decrease as after the capsulotomy operation, except in my experience in one case in which hyaloid opacity followed. Striped keratitis, in my opinion, depends as much on the use of strong percentages of cocain and on bichlorid solution or ointment as on the rubbing of the cornea. I beg to correct one of the speakers in that my statistics were somewhat distorted by him. I remarked that I did 154 cataract operations, of which 40 were expression operations, within the course of two years, and printed in the paper is a report of 10 cases out of the 40 with loss of vitreous, making 25 per cent., not quite so good as Smith's, instead of "better." The meat of the cocoanut of this discussion was the fact that this is a better operation for cataract than all others but must be done by skilled men, and even oculists of much experience will have to learn the technic by getting down to pigs' or, preferably, rabbits' eyes, because the lens of the rabbit's eye is more like that of the human eye, and acquire dexterity before operating on the human eye.

Dr. D. W. Greene, Dayton, Ohio: I wish to impress on the members of the section that I have approached this subject in the spirit of a student. I have made 145 cataract extractions since the first day of last August. All except 5 of these have been by this method, so I need hardly tell you that I have not selected the cases. I am not here to champion the Smith operation. Smith will have to take care of that, and ophthalmologists who have sufficient opportunity will have to settle the future of the operation. I am impressed with the operation and the results I have had from it, and I shall continue to practice it until I see some better reason than I have yet seen to depart from it.

In regard to Dr. Callan's statement regarding the pressure, I think that is a point where men make a mistake. There is no great pressure applied. Dr. Casey Wood will bear out this statement. He manipulated the hook in one case, and the lens described all the versions seen in the diagrams and came out whole. Dr. Jackson did the same thing. There was no loss of vitreous. It is not so much the pressure as the manipulation that delivers the lens. Men get an exaggerated idea of it. You have an empty anterior chamber and you are pressing against a soft bag, so to speak, and there is nothing behind to resist you except the vitreous, hence the manipulation seems excessive.

Some one spoke of Major Smith operating on these patients and never seeing them again. He says that is absolutely untrue, but that in India they will hunt him up and he sees them more frequently than he wishes to. I have seldom seen the iris prolapse in healing. This accident is usually associated with high blood pressure, which I have reduced whenever possible.

As to the visual results another mistake is easily made; if you test these cases as after an ordinary cataract operation, you will be disappointed. Visual results, like old wine, get better with age, and one should not refract these patients under thirty days after the operation. Three years ago I reported twenty-two cases of so-called Smith operation at Oakland, Mich. I had one case of glaucoma occurring between my visits to the National Military Home. I visit the Home on Tuesday afternoon, and not again until Friday afternoon. In the meantime, the cases are under the care of an assistant, who is not an oculist. He is a member of the medical staff, and I take him as an assistant for a year and teach him all that I can. This case of glaucoma occurred between my visits and the eye was lost. The other case of glaucoma came on a year after the operation and I do not think had any connection with it at all. These make 98 patients whom I have operated on with one case of glaucoma, up to the time my statistics were compiled.

In regard to keratitis I have been awkward enough to get it, but less frequently now than when I began the operation. If one will make steady pressure and manipulate the hook properly and keep away from the center of the cornea and deliver the lens quickly he is not likely to get it. Thirty to forty years ago Pagenstecher noted the presence of lattice keratitis and also a disturbance in the anterior layers of the vitreous which I have also seen, but they have always cleared up in my experience.

Visual results are better than by the old method and have remained better so far as I have watched them. The future of this operation, depends entirely on visual results. I do not know the future of this method, I am not here to tell you that the smallest loss of vitreous does not harm. I know better than to do that. We do not yet know what the ultimate result of loss of vitreous will be. We have no statistics to determine it, Major Smith is not in a position to determine it definitely, and pathologists can not help us. I can only say that I have not seen any harm result from the loss of one-third up to this time. The future of the method depends on how the profession in this country, men of broad and liberal minds with large operating fields, will accept it. If they are ready to take it up and follow it to its legitimate conclusion, we will soon know its place among cataract operations, which will be largely determined by the percentage of vitreous loss and the harm, if any, which ultimately results from moderate loss. In my opinion, these questions will never be settled by theoretical or *a priori* reasoning, but must be settled by cold statistical facts and figures.

SECTION COMMITTEE REPORTS

[EDITOR'S NOTE: The following reports of committees were presented before the Sections at the Atlantic City Session, June 7 to 10, 1909. They are referred to in the minutes of the Sections which appeared in THE JOURNAL, July 3.]

REPORT OF THE COMMITTEE ON THE REVISION OF THE PHARMACOPEIA [*]

It has not been the aim of this committee to do more than bring forward what seemed to be the changes which might advisedly be made in the revision of the Pharmacopeia from the standpoint of the clinician. There are many points which the general committee on the revision have to consider which do not specially concern us. As is well known there are many interests to be considered, perhaps how many only those on the committee have any idea. The discussions of these, however, is not in place here, and it seems advisable to take up only those points which may profitably be considered by the clinician.

What should the Pharmacopeia include? Should it be kept to the smallest limits or allowed to expand? Should every drug which is included in it be carefullly scanned at intervals to see if its position is still deserved? Should additions be looked at with careful scrutiny or should we go on the principle that everything which the profession uses should be included? Should combinations of drugs be admitted or not? Should proprietary or patented remedies be admitted to it? Should Tct. X Co. be in the Pharmacopeia when Tct. Y Co is not? Ask yourself some of these questions put them to your friends and you begin to realize how many views there are. It is probably not our province to pass on these, but still we may say something.

Under the title, "The Capture of the Pharmacopeia; With Suggestions for its Recapture," Leffman[1] has pointed out what a small proportion of the committee on the last revision was composed of clinicians, the majority being pharmacists. A reversal of these numbers would seem to be in order—yet it can safely be said that the majority of the profession take little interest in the Pharmacopeia, know little about it, and do not feel that it really concerns them. This is a matter which we should regard very seriously and anything which can aid in making the Pharmacopeia more used as a handbook by the profession is well worthy of consideration. Of course there are many causes for this and the remedy lies in various lines, such as the proper instruction of students in their attitude towards and knowledge of it. But these hardly come in the province of this discussion.

It will be granted that it would be a great advantage to have the profession more familiar with it and as far as possible using the drugs therein contained. That there are certain drugs which will be used and can not be admitted is evident. For one thing the revision takes place only at intervals and new substances protected by a trademark or patent must be considered. At present many of them are in extensive use. But the great bulk of the drugs which we need to use are found in it. Probably a certain number of the profession will use substances or combinations which can never be admitted. The more they know about the Pharmacopeia the fewer will belong to this class. To have the Pharmacopeia used more extensively by the profession seems an important matter and the more convenient it can be made, the more closely we can bring the drugs in it to correspond with the ones in active use, the better.

An important point which should be kept in mind is the possibility of making the Pharmacopeia something which will come into constant use by the members of the profession generally. In bringing this about one important thing is the reduction in size, which seems to be a point worth considering. Might it not be possible to omit the appendix? The reply may be made that this is an integral part of what the Pharmacopeia should be and yet for the medical profession it is of little importance. Perhaps an edition for the profession might be published in which the various directions regarding preparations, which belong more strictly to the pharmacy side, might be omitted. Another point which is put forward for discussion is in regard to the publication of an annual bulletin, such as has been brought out by the American Medical Association. The value of this to the profession has been tremendous and we owe a great many thanks to those who have done the work of its preparation. Would it be possible to have a somewhat smaller publication in association with the Pharmacopeia brought out every year or every second year? If this were done the profession would probably regard the Pharmacopeia more as a volume dealing with everyday things than as a record of the past. It may be the general opinion that this is better left to the American Medical Association, but the advisability of the other course seems worthy of consideration. This would not exclude the work at present being done and might be carried on in conjunction with it.

Another point is as to the advisability of introducing any substance "which cannot be produced otherwise than under a patented process or which is protected by proprietary rights." The advisability of doing this is hinted at in the eighth Pharmacopeia. Your committee feels that this would be a mistake and that the position taken in the last Pharmacopeia should be maintained. To do otherwise is to admit the thin edge of what would prove to be a very large wedge. Certain drugs might be omitted without any harm being done but who is to draw the line? It seems safer to hold by the present rule; there is less danger in that than in the other case. How many of the preparations which would have been admitted ten years ago, would be considered worthy of a place to-day? How many which might be regarded as worthy of a place to-day would be retained ten years from now? At the same time one must recognize that there is much to be said for the other view, that under proper safeguards some of them might be admitted.

---

[*] Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[1] Read before the Philadelphia County Medical Society, March 24, 1909.

Drugs which should be dropped from the Pharmacopeia. It may be thought well to retain some of these in the National Formulary for various reasons. The majority do not seem to deserve a place and should be dropped for want of sufficient recognition and use. Some are used in certain localities, but *this should not justify their retention.*

Acetum Opii.
Acidum Camphoricum
Aconitina: (This should be dropped on account of its strength and variability as well as the dangers of poisoning.)
Adeps: (The use of this has almost entirely ceased. It has been replaced by more suitable substances.)
Althea.
Anthemis.
Berberis: Fluidextractum Berberidis.
Calamus: Fluidextractum Calami.
Calendula: Tinctura Calendulæ.
Cassia Fistula.
Chimaphila: Fluidextractum Chimaphilæ.
Chirata: Fluidextractum Chiratæ.
Cimicifuga: (Tincturæ Cimicifugæ; Fluidextractum Cimicifugæ; Extractum Cimicifugæ.)
Cinchonidinæ.
Cinchoninæ Sulphas.
Cypripedium: Fluidextractum Cypripedii.
Euonymus: (Fluidextractum Euonymi; Extractum Euonymi.)
Eupatorium: Fluidextractum Eupatorii.
Frangula: Fluidextractum Frangulæ.
Gambir: (Tinctura Gambir Composita; Trochisci Gambir.)
Geranium: Fluidextractum Geranii.
Hedeoma: Oleum Hedeomæ.
Krameria: (Tinctura Krameriæ; Fluidextractum Krameriæ; Extractum Krameriæ; Syrupus Krameriæ; Trochisci Krameriæ.)
Lappa: Fluidextractum Lappæ.
Linimentum Saponis Mollis: (This causes confusion as it is not *intended to be used as an embrocation.* The same might be changed.)
Marrubium.
Matico: Fluidextractum Matico.
Matricaria.
Mezereum: Fluidextractum Mezerei.
Oleum Coriandri.
Oleum Erigerontis.
Oleum Sabinæ.
Oleum Sinapis Volatile.
Pareira: Fluidextractum Pareiræ.
Phytolacca: Fluidextractum Phytolaccæ.
Pimenta: Oleum Pimentæ.
Piperina.
Pulvis Acetanilidi Compositus: (There does not seem any reason [illegible] n.)
[illegible] illajæ: Tinctura *Quillajæ*)
[illegible] Rhois Glabræ.
Rubus: (Fluidextractum Rubi; Syrupus Rubi.)
Sabal: Fluidextractum Sabal.
Safrolum.
Salvia.
Scutellaria: Fluidextractum Scutellariæ.
Staphisagria: Fluidextractum Staphisagriæ.
Stillingia: Fluidextractum Stillingiæ.
Unguentum Potassii Iodidi.
Unguentum Zinci Stearatis.
Unguentum Hydrargyri and Unguentum Hydrargyri Dilutum: (Much confusion is caused by these *two* ointments and one should be dropped.)
Xanthoxylum: Fluidextractum Xanthoxyli.

In regard to the question of *additions*, the committee recommends that the physiologic standard for the strength of certain drugs be adopted. Among these we should suggest digitalis, strophanthus and ergot. At present various methods are used, and it would seem wise that a definite standard should be laid down. Regarding the drugs which should be added, the following seem worthy of consideration:

Calcium Lactate: This is being used more and more and is rapidly replacing calcium chlorid.

Phenolphthalein: This has come quite extensively into use and its value seems to be definitely established. It might possibly be wise to add the preparation which can be given hypodermically.

Arsenic: The use of arsenic has increased a great deal of late, especially its hypodermic administration, and it seems wise to have some preparations in the Pharmacopeia which can be readily used in this way. Of these the value of sodium cacodylate and sodium aminophenyl arsenate seems definitely established.

Theobromin: The value of this seems sufficiently established.

Bile Salts: The suggestion that their inclusion be considered seems worthy of consideration.

Diacetyl-morphin and *Theobromin-sodio-salicylate* are extensively used and worthy of being added.

It may seem that the number of drugs to be included is in striking disproportion to the number struck out. The overgrown condition of the Pharmacopeia supports the advisability of this. There seems good ground for the feeling that we should go slowly in adding to what has too much already.

Joseph A. Capps, Chicago.
Joseph H. Pratt, Boston.
Thomas McCrae, Baltimore.
John T. Halsey, New Orleans.

ABSTRACT OF DISCUSSION

Mr. M. I. Wilbert, Washington, D. C.: From a pharmaceutical point of view the report is a very pleasing one. There can be no doubt but that members of the medical profession *should absolutely dictate the contents of the Pharmacopeia.* That is their province, it is their duty. The Committee on Revision of the Pharmacopeia is often mistaken for the revision convention. We frequently hear that the clinician, the medical practitioner, is not represented on the revision committee; as a matter of fact the clinician requires no representation on the revision committee at all. There is nothing in connection with the work of the revision committee that is of any direct interest to him, or to which he can contribute materially; he would hamper rather than aid the work of revision. The medical profession should dictate what the Pharmacopeia should contain and the method of providing it.

Much has been said about the size of the Pharmacopeia. Here again the medical man should insist that a more distinct division be made between pharmacopeial matters proper and the chemical tests. Much of the material now in the Pharmacopeia itself could be relegated to this appendix, and thus divide the Pharmacopeia into two volumes; one the Pharmacopeia proper which the physician could use and which would contain all the information he wanted, while the combined volumes should contain all the information the pharmacist needs and must have. As the report states, the function of the Pharmacopeia is primarily one of standards; it should be simply one of standards and not a medical lexicon. If the standards are correct they do not need changing annually and only such changes need be made as are found necessary to correct palpable errors. The more or less ephemeral drugs are sufficiently well defined by the Council on Pharmacy and Chemistry of the American Medical Association in "New and Nonofficial Remedies."

Ninety years ago, when the United States Pharmacopeia was originated, it was in the hands of medical practitioners who had a wide scope of vision. They wished to make the book valuable and to keep it in harmony with the standards established abroad. Singularly enough, that idea prevailed until the Pharmacopeia came to be revised by pharmacists and converted into a book on pharmacy. In 1902, an international congress was held in Brussels for the purpose of establishing standards for potent medicaments. Among the articles acted on was mercurial ointment; a 33 per cent. ointment of mercury was adopted as an international standard. The Committee on Revision of the United States Pharmacopeia, in attempting to comply with the international requirements, introduced a diluted mercurial ointment, or blue ointment, which, by the way, is not blue at all, but green, and does not comply with international standards except so far as its strength is concerned. If the Pharmacopeia is to meet the needs of the medical profession true international standards must be insisted on.

I wish to congratulate the profession on the tone of the report. If the medical practitioners of the country will assume a more dictatorial policy, the next Pharmacopeia of the United States will be of value to the medical man and a real necessity to the pharmacist.

Dr. Lewis A. Conner, New York: The difficulties attending the selection of the more or less obsolete drugs to be dropped from, and the new drugs to be added to, the Pharmacopeia are many and great. The recommendation of the committee as to the drugs to be dropped will, I think, be generally approved. They can all well be spared. The number of drugs recommended for admission, however, is, it seems to me, regrettably small, and the reason for this lies in the fact that the committee has decided not to recommend any drug which has been patented. However much we may prefer to use unpatented drugs, the fact remains that practically all the modern, synthetic drugs are so patented, and among this number are many remedies in constant, daily use, which could not be dispensed with without the serious crippling of our therapeutic resources. Such drugs, for example, as aspirin, adrenalin, argyrol, heroin, ichthyol, veronal—to mention only a few out of many—shall we abandon their use merely because they are patented? I think few would venture to recommend so radical a course. But, if we are to continue to use them, should they not, if they have proved their usefulness, have a place in the Pharmacopeia? It seems to me that they should.

It will be generally admitted, I think, that the Pharmacopeia at present fails to meet the needs of the practicing physician and has lost its position as guide and book of reference in his daily work. The reason for this is chiefly that in it he seeks in vain for information concerning many of the drugs is general use. It is idle to expect that he will abandon the use of drugs merely because they are not to be found in the Pharmacopeia. It is much more likely that he will discard the Pharmacopeia itself. One of the very best evidences that the Pharmacopeia does not at present meet the requirements of physicians is the fact that this Association has felt it necessary to publish the two admirable little volumes, "Physicians' Manual of the Pharmacopeia and National Formulary" and "New and Nonofficial Remedies."

If the Pharmacopeia is to regain its position of prestige and usefulness, so far as it concerns physicians, some radical changes in its policy are necessary. In my judgment, the most important of these are: First, the publication of a greatly abridged "Physicians' Edition," as has been suggested by Mr. Wilbert. Second, the inclusion of the more trustworthy and useful of the modern, synthetic drugs, whether they be patented or not. Third, the issuance at frequent (perhaps yearly) intervals of bulletins recording the changes which have been made, the new drugs introduced, the undesirable ones dropped. With the enormous yearly output of new drugs, a certain small proportion of which are really valuable, it is idle to suppose that a volume of this sort which is revised only once in a decade can keep abreast of current practice. The needed flexibility can be obtained, I think, only by the publication of such bulletins at comparatively short intervals.

Dr. John F. Anderson, Washington, D. C.: One very important agent has been omitted from the list of proposed additions to the Pharmacopeia, namely, tetanus antitoxin. Diphtheria antitoxin was admitted to the Eighth Decennial Revision of the Pharmacopeia following the promulgation of a standard unit for diphtheria antitoxin by the U. S. Public Health and Marine-Hospital Service. On Oct. 25, 1907, a standard American unit for measuring the strength of tetanus antitoxin was promulgated by the same laboratory. The great value of tetanus antitoxin as a prophylactic alone certainly entitles it to admission to the Pharmacopeia, and I hope that it will be included in the next revision.

Dr. M. Clayton Thrush, Philadelphia: A smaller edition of the Pharmacopeia for the use of clinicians should include the Latin and English name of each drug, its synonym, a description of the important characteristics of the drug, its dose, solubility and compatibility, with therapeutic action expressed in a few words, and a few other particulars; which is all the average clinician wishes. Such a book could be bought for about fifty cents. A book entitled the "Physicians' Manual of the Pharmacopeia and National Formulary," published by the American Medical Association, contains those very facts; it is a small book and gives the official name, synonyms, characteristics, doses, therapeutic indications, etc. This is really all the physician needs. Therefore, why not supply ourselves with such a manual; in it could be inserted year by year the drugs that the Council on Pharmacy and Chemistry has examined and recommended.

With regard to the admission of new drugs, there is one drug that is largely used at the present time and under so many different names, viz., the active principle of the adrenal gland. This is supplied under different names by the different manufacturers, but all preparations are of the same strength, 1 to 1,000 in normal salt solution. Why not make this official? At present the gland itself only is official. But only about one physician in one thousand uses the gland; all others always use the active principle. It is certainly difficult to decide what is best to add, and what to dismiss.

With regard to dismissals, with such drugs as saw palmetto, for example, there is much adverse criticism. Hallberg collected one million prescriptions in order to show what drugs were most used in this country. He found that saw palmetto, while only prescribed about three times in a thousand prescriptions in Philadelphia, was prescribed over thirty times in Chicago, and so it is with all those drugs if we but investigate. There are drugs used in one portion of the country that are not at all used in another portion. A Pharmacopeia should not be one designed for Philadelphia alone, but for the United States. Therefore, it is important that all the drugs in use all over the country should be included. Here is another point that should be borne in mind; while these drugs are practically of no use, I believe they should be placed in a special place and not entirely dropped, for they may be of some service to certain practitioners in certain localities.

Report of the Committee on Proposed Alterations in the United States Pharmacopeia *

Your committee, appointed by the Chairman of this Section to examine into the merits of various remedies alleged to be of value in ocular diseases, begs to make the following report:

With a view of choosing what seems to be of distinct value to the practitioner and, as such, proper additions to the United States Pharmacopeia of 1910, they decided to settle the matter by a vote of members of the Section. As a preliminary to this action, it was resolved to consider only those remedies that had been investigated by the Council on Pharmacy and Chemistry of the American Medical Association. As is well known, most of the remedial agents recently recommended, generally in glowing terms, to the ophthalmologist are strictly proprietary. As a rule, neither the trade name nor the literature sent out by their owners, gives more than an inkling of their real character, nor do they throw any light on the process of manufacture. He who prescribes such a remedy is altogether in the dark in these important particulars, and might almost as well study his therapeutics in the advertising columns of a trade journal. Fortunately, we have an agency (for which we have mainly to thank Dr. Leartus Connor and its present secretary, Dr. George H. Simmons) that analyzes the constituents and reports on the pharmacal and therapeutic characters of every drug that gains, by advertisement or other means of exploitation, any considerable degree of notoriety or public favor. We refer to the Council on Pharmacy and Chemistry whose reports are published, first of all in The Journal, and subsequently in a periodical entitled "New and Nonofficial Remedies." The great majority of new proprietary and other remedies exploited during the past ten years have been investigated by the Council and described in this publication.

From the long list of drugs thus treated your committee first chose fourteen, as representing the most desirable additions to the new Pharmacopeia from the purely ophthalmic standpoint. After some consideration of the subject, it was decided that this number might well be reduced to six. To this end a postal-card vote of the Section (about 930 members) was taken with the following result:

Adrenalin hydrochlorid received	552 votes
Dionin	538 votes
Argyrol	474 votes
Fluorescein	407 votes
Protargol	285 votes
Holocain hydrochlorid	257 votes

The variation in these numbers is to some extent explained by the fact that quite a few members voted for fewer than six remedies—a proceeding that has the sympathy of a portion of your committee, who feel that extreme caution should be exercised in giving official sanction to any new remedy; especially to one that has not satisfactorily stood the test of time.

In our opinion the ophthalmologist may easily dispense with some ocular remedies official in the Pharmacopeia of 1900, and this fact might be profitably urged on the Revision Committee in 1910. Among these your committee would suggest the following, as having fallen into general disuse, and we recommend that they be dropped from the revised Pharmacopeia:

Argenti nitras mitigatus or "mitigated stick;" the oleate of cocain; the oleate of atropin; the salicylate of physostigmin (eserin); the Extractum Scopolæ and the Extractum Stramonii.

---

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

It is further recommended that, admitting the therapeutic value of hyoscin hydrobromid, scopolamin hydrobromid be dropped; that it is not necessary to retain two salts of hyoscyamin and that either the sulphate or the hydrobromid be rejected by the Committee on Revision.

Finally, the Council on Pharmacy and Chemistry of the American Medical Association has recently asked your committee the following question: "Does homatropin hydrochlorid offer any advantages over the official homatropin hydrobromid, or does the latter answer for all purposes?" As this committee has before it no reliable data on which to estimate the relative merits of these two salts, it was decided to submit the matter to the Section, declaring at the same time its belief that homatropin hydrobromid appears to meet all the demands made on it as a satisfactory ocular remedy. It has few objectionable incompatibilities, does not readily undergo decomposition, is very soluble in ordinary menstrua, is practically non-irritant, and is readily absorbed by the ocular tissues. *A priori*, there seems to be no reason why it should be displaced by the hydrochlorid.

All of which is respectfully submitted.

Edward Jackson. Casey A. Wood, Chairman.
T. B. Schneideman. A. Edward Davis.

Preliminary Report of the Committee for the Study of the Relation of Tuberculosis to Certain Diseases of the Eye [*]

The Chairman of the Section requested me to form a committee for the collective study of the relation of tuberculosis to certain diseases of the eye whose etiology is in many cases obscure. It was thought that a number of observers could in time accumulate enough data to draw conclusions that might not be warranted by the smaller number of cases that would be available to a single individual. The following gentlemen have signified their interest in the subject and their willingness to engage in the work of investigation according to the plan agreed on:

C. S. Bull, New York City.
Arnold Knapp, New York City.
F. Park Lewis, Buffalo.
L. Webster Fox, Philadelphia.
W. C. Posey, Philadelphia.
G. E. de Schweinitz, Philadelphia.
H. F. Hansell, Philadelphia.
Harry Friedenwald, Baltimore
R. L. Randolph, Baltimore.
Hiram Woods, Baltimore.
G. S. Derby, Boston.
W. H. Roberts, Pasadena.
Melville Black, Denver.
David H. Cooper, Denver.
H. C. Parker, Indianapolis.
A. E. Bulson, Fort Wayne, Ind.
L. W. Dean, Iowa City.
E. R. Lewis, Dubuque.
W. H. Wilder, Chicago.
Charles H. Beard, Chicago.
E. V. L. Brown, Chicago.
William E. Gamble, Chicago.
H. Gradle, Chicago.
C. D. Wescott, Chicago.
Oscar Dodd, Chicago.

The committee will be pleased to have the cooperation of others who will study cases according to the plan outlined, keeping careful records on blanks prepared for the purpose. The examination of patients with eye disease suspected of being tuberculous is made according to the following outline:

EXAMINATION OF CASES WITH DISEASE OF THE EYE FOR SUSPECTED TUBERCULOSIS

1. A thorough physical examination of nose, throat, lungs, joints, etc.
2. A careful statement of the diseased condition of the affected eyes.
3. Examination with tuberculin.
   (a) *Cutaneous Test:* One drop of old tuberculin to be gently rubbed into two scarified points on the arm about 5 cm. apart. For control one drop of 0.5 per cent. carbolic glycerin should be gently rubbed into a scarified point midway between and a little to one side of the line of the other points.

   °Tuberculin.
   °Control.
   °Tuberculin.

   The scarified point need not be over 1/12 inch in diameter and care should be taken not to draw blood, but to see that serum begins to exude.

   (b) *Conjunctival Test:* This should be practiced simultaneously with the cutaneous test if one is to all appearances sound and there is no history of previous disease in it. One drop of 1 per cent. solution of old tuberculin in physiologic salt solution should be dropped into the conjunctival sac, and the patient's eyes kept closed for three minutes. The case should be observed twelve hours, twenty-four hours and forty-eight hours after the test to note the reaction, if any.

   Reactions: Time when reaction to cutaneous test occurs should be noted, and the case should be seen in the first twenty-four hours. Size of areola should be measured in millimeters and the intensity of the reaction noted. Temperature should be taken and general condition noted. Vaccination point should be observed twenty-four and seventy-two hours after test, especially if reaction is delayed. The degree of conjunctival reaction should be noticed within twelve hours after the test and a careful record kept of its character and duration so as to compare with cutaneous test. If both these tests are negative at first they should be tried again in the same manner after three or four days. If the tests are still negative, and the observer has reason to suspect that the case, from its clinical appearance, is of tuberculous origin, the subcutaneous test should be used.

   (c) *Subcutaneous Test:* The patient should be in the hospital, or may be instructed (if intelligent enough) to take his own temperature at home. The temperature should be taken every two hours for two days prior to the injection. If it is found to be normal the test may be practiced according to the method of Koch. One mg. of old tuberculin first injected. If result is negative at the end of three days, 3 mg. may be used. If the result from this is negative at the end of three days a 5 mg. dose may be used. If this is negative one may assume that active tuberculosis does not exist. If result is positive a record of the temperature should be made every two hours and the character of the reaction described. Particular notice of the affected eye is important to see if a local reaction is present. This should be indicated by increased ciliary injection or an aggravation of the original trouble. Careful note should be taken also of the point of puncture, for reaction here is very delicate.

It is thought that the following diseases may be profitably studied by this method: Blepharitis, particularly chronic, ulcerative cases; chalazion; follicular conjunctivitis or adenoid hypertrophy of conjunctiva; phlyctenular disease of the conjunctiva and cornea; scrofulous pannus; interstitial keratitis (non-syphilitic); episcleritis; scleritis; sclerosing keratitis; chronic iritis and iridocyclitis when etiology is obscure (relapsing or recurrent forms are especially suspicious); uveitis with hyalitis; choroiditis.

If several observers are working in the same hospital, it would be convenient to have all cases of one kind assigned to one man in order to simplify the work. This, however, is a question of convenience. All the observers engaged in this work are supposed to use in their tests tuberculin from one factory, that of H. M. Alexander & Co. It is hoped that at the next meeting, as a result of this cooperative work, there may be something of interest to report.

William H. Wilder, Chairman.

Report of the Committee on Collective Investigation Concerning the Ocular Muscles [*]

Almost immediately after the chairman of this committee was asked to undertake the work he associated two others with himself, Dr. Howard F. Hansell of Philadelphia, and Dr. Edward Jackson of Denver. The latter found it impossible to continue on the committee, and later his place was taken by Dr. T. B. Schneideman of Philadelphia.

The first step was to ascertain who were at all interested in such a study. Accordingly a circular letter was issued to each member of the Section on Ophthalmology. A copy of this letter is here appended as Exhibit A.

The total number of replies received to this was one hundred and twenty-five. It was gratifying to find that every member thus replying expressed approval of the effort, although forty found it impossible for various reasons to join in the study. An examination of these replies and certain considerations led the committee to decide that it was advisable to study several unanswered questions concerning the anatomy and physiology of the muscles, before attempting any cooperative investigation relating to their pathology.

---

[*] Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[*] Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Accordingly, a series of twenty-four questions was drawn up with considerable care, and different groups of the members were asked to investigate these different points. The letter explaining more in detail the scope and the general outline of the work, is also attached with this report, and is marked Exhibit B. Several of the members did not find the questions which were assigned to them entirely of their taste, and were accordingly asked to take other questions for study.

In making these arrangements, the committee has therefore sent out about 850 of the first circular letter and 85 of the second circular letter, and in addition has written thus far about 130 letters.

As a result, however, we have now over 80 members who are studying with more or less exactness these different questions concerning the anatomy and physiology. It is probable that a number finding that any real work demands time and patience will promptly give up the effort; but it is also probable that some will persevere, and we shall be able in this way to establish a certain few underlying facts. These, with other data which we already have, will give a broader and firmer foundation for any study of the pathology of the muscles, which may be elaborated by members of our section or by others in the future.

COMMITTEE ON THE COLLECTIVE INVESTIGATION OF QUESTIONS CONCERNING THE OCULAR MUSCLES

183 Delaware Ave., Buffalo, N. Y., December, 1908.

My Dear Doctor:—At the last session of the American Medical Association, Dr. Wilder, then the chairman of the Section on Ophthalmology, advocated the same system of collective investigation for that Section as had been adopted with advantage in other societies.

In acordance with that suggestion Dr. Alvin A. Hubbell, present chairman of the Section, has constituted the undersigned a committee for the collective investigation of questions concerning the ocular muscles. For the sake of uniformity this committee will not only select the question or questions for study, but arrange other details of the work. If sufficient interest is shown in the subject by members of the Section, various phases of different questions could be studied by different subcommittees. In any case, however, the results obtained by each individual would be kept separate. The object is not to deal with theories, but to collect FACTS, which are carefully observed and accurately recorded. As every ophthalmologist meets daily with unsolved problems concerning the muscles, perhaps some data can ultimately be obtained which would be useful to all, without great effort on the part of any one.

The committee hopes to keep the bibliography of the subject complete, and to make it useful to students whether they cooperate in this investigation or not.

The Section will probably confirm the action of the Chairman in making permanent these committees on special investigation. If that is not done, the work could continue just the same, and if the results are of any value, ample opportunity would be afforded for publication.

Instead of confining the effort to a few, it seems best to issue this circular letter inviting the cooperation of every one in the Section. Among the younger members, especially, there are probably many who have not only the time and energy, but the training necessary for such work.

If, therefore, you are sufficiently interested to cooperate, even to a slight extent, please answer the following questions, and mail them in the enclosed envelope before the middle of December.

Lucien Howe, Buffalo N. Y.
Howard F. Hansell, Philadelphia.
Edward Jackson, Denver.

1. Do you care to take any part in the proposed collective investigation of some question concerning the ocular muscles?
2. What suggestion have you to make if any, as to which aspect of the subject could be studied first to best advantage?
3. Have you any preference as to exactly which part of that question or any other you would like to have assigned to you?
4. Have you opportunities for work if desired, in some well-equipped laboratory? If so, is that physiologic, pathologic, ophthalmologic or of what kind?
5. Are you connected with any hospital or dispensary?
6. Have you access to a good medical library, or can you obtain books through some incorporated library, from the library of the Surgeon-General?
7. Have you an easy reading knowledge of German or French or both?

COMMITTEE ON THE COLLECTIVE INVESTIGATION OF QUESTIONS CONCERNING THE OCULAR MUSCLES

183 Delaware Ave., Buffalo, N. Y., January, 1909.

My Dear Doctor:—The committee on the investigation of questions concerning the ocular muscles wishes to acknowledge your reply, and that of many others, offering to cooperate in the proposed study.

The nature of these replies, with other considerations, have convinced the committee that it would be worse than useless to attempt to deal with phases of pathology or treatment, until we can first agree on certain propositions, still doubtful, concerning anatomy and physiology.

The following general plan has therefore been adopted, for the beginning:

1. A given question will be placed, if possible, in the hands of some colleague who has already studied it, or who has expressed a desire to study it.

2. Each colleague is expected to obtain cooperation from others, physiologists, chemists—any one, anywhere—only being certain that apparent facts are really facts, accurately observed and carefully recorded.

3. In physiologic experiments the term "normal eyes" will be understood as those whose manifest ametropia does not exceed 0.05 D., whose proximate point is in proportion to the age, the individual being in good health and entirely free from asthenopic symptoms.

Experience has shown that it is most convenient for a student of these questions to use his own eyes for experiment, if they are sufficiently near the normal type; if not, the eyes of some member of his household. Typical subjects for study can usually be found among soldiers (including members of the National Guard), or others who lead an out-of-door life.

4. For the sake of uniformity each subcommittee or individual is expected to report to the central committee, if requested, two or three times a year concerning the progress made.

5. As accuracy and truth are the prime considerations, it is not desirable to hurry to conclusions. But if a given piece of work in the hands of a subcommittee or of an individual lags unnecessarily, some one else will be invited to study that question.

6. A colleague can feel free to publish his work anywhere and at any time. But if it is to form a part of any report formulated by this central committee, then

A. The article must be in the hands of this committee at least four months before a meeting of this Section.

B. If it has been already published, only a brief abstract would be made of it—sufficient to show its value as a link in the chain of facts.

C. If it has not been already published, an abstract will also be made, but the communication, with abbreviations, if necessary, would be referred to the committee on publication, in order that it may form part of the Transactions of the Section.

7. The central committee, if requested to do so, will furnish references to the bibliography of the questions proposed by them.

If you wish to join in this investigation will you please inform the chairman of this committee before the — of January whether:

A. You will accept the suggestion to study the question given below; or

B. If you prefer some other question, please state what it is.

The central committee appreciates that many who promptly accepted the invitation expecting to make clinical observations, will not care to study first anatomy or physiology. The cooperation of such colleagues must therefore be deferred or unfortunately lost entirely.

But the favorable replies to the first circular letter have been sufficiently numerous, and from men of sufficient standing, to warrant the hope that those who do cooperate will be well repaid by the satisfaction of contributing a little to our knowledge, and by the honor of being connected with a work which may ultimately prove of some credit to American ophthalmology. Truly yours,

The Committee,
Lucien Howe, Buffalo.
Howard F. Hansell, Philadelphia.
T. B. Schneideman, Philadelphia.

Report of the Committee of Revision of the United States Pharmacopeia *

To the Chairman and Members:—Your committee takes pleasure in presenting the following report on the revision of the United States Pharmacopeia. Perambulatory, it may be remarked that the committee has restricted its work to such drugs as are generically termed "dental remedies."

PROPOSED ADDITIONS

General Anesthetics: Nitrous oxid gas in its pure state or combined with oxygen is by far the most used general anesthetic in dental surgery. On account of its relative safety and quick action, it is especially adopted for those cases of minor surgery in which a general anesthetic is indicated Liquid nitrous oxid gas and liquid oxygen are recommended for adoption in the U. S. P. Recently, various mixtures of general anesthetics which are principally composed of ethyl chlorid, methyl chlorid and ethyl bromid have been freely discussed in current dental literature. These mixtures are not recommended for admission to the U. S. P., as they offer no material advantage over pure ethyl chlorid. The latter drug has been admitted to the eighth decennial revision of the Pharmacopeia.

Local Anesthetics: Ever since the introduction of cocain as a local anesthetic, chemists have been busy looking for substitutes to overcome the many side-effects of cocain as pointed out to them by the clinicians. Of the many substitutes offered, the following are the most important ones: Alypin, anesthesin, the eucains, holocain, novocain, the orthoforms, stovain, tropacocain and chlorbutanol (chloretone). After a careful investigation of these various products, novocain (see New and Nonofficial Remedies) seems best suited for anesthetic purposes in dental surgery. It is five or six times less poisonous than cocain, absolutely non-irritating to the tissues and of an equal anesthetic power when combined with the alkaloid of the suprarenal capsule. For external application the orthoforms deserve to be recommended. On account of the relatively low poisonous nature of novocain, the latter may be successfully used as a substitute of the orthoforms. Novocain is to be recommended for admission to the U. S. P.

The addition of the alkaloid of the suprarenal capsule to local anesthetics has placed the administration of these latter chemicals on a comparatively safe basis. According to modern conception, rational local anesthetization of the oral tissues is safely and effectively accomplished by the combined action of the anesthetic and of an agent which produces local anemia. The alkaloid of the suprarenal gland is eminently suited for this purpose. Recently, a synthetic product has been introduced as a substitute of the natural alkaloid of the suprarenal capsule. The admission of the alkaloid of the suprarenal capsule or its synthetic substitute and their solutions is to be recommended to the U. S. P.

The Antiseptics: Among the modern organic metallic salts used as antiseptics, the silver compounds occupy a prominent place. Of the many preparations, only two are mentioned here, for the reason that they have shown real merit and that they are apparently more in general favor than the balance. They are protargol and argyrol. One or the other of these preparations is recommended for admission, the selection is left to the discretion of the proper committee of the revision of the U. S. P.

Among the many new compounds which evolve nascent oxygen, magnesium dioxid and sodium perborate deserve to be mentioned. Magnesium dioxid may be advantageously added as an antiseptic to tooth powders. Its advantage over other oxygen compounds (calcium or strontium dioxid, etc.) is obvious. Sodium perborate, when dissolved in water, furnishes an alkaline solution of hydrogen dioxid of a fairly reliable strength (with limitations).

Recently a stable 30 per cent. solution of hydrogen dioxid has been introduced under the name of perhydrol (see New and Nonofficial Remedies). It is free from acid and may be mixed with water in all proportions. For dental purposes, it is far superior to the concentrated ethereal solution of hydrogen dioxid and is comparatively free from danger. It is especially serviceable as a bleaching agent and as a caustic. Magnesium dioxid and perhydrol are recommended for admission to the U. S. P.

Trioxymethylen, a polymerized form of formaldehyd gas (see New and Nonofficial Remedies), has been employed in operative dentistry with so many gratifying results that it deserves to be recommended for admission to the U. S. P.

Soap solutions containing formaldehyd gas in definite quantities have been largely used as hand and instrument disinfectants and have proven to be very efficacious. These solutions have certain advantages over other solutions which are used for this purpose, viz., the compound cresol solution, as being comparatively odorless. A solution of this nature corresponding to veroform (see New and Nonofficial Remedies) deserve to be recommended for admission to the U. S. P.

The eighth decennial revision of the Pharmacopeia has admitted a preparation known as Liquor Antisepticus, apparently as a substitute for the many proprietary preparations of a similar nature. The taste of the official preparation is unpleasant, and, as taste is a very important item in regard to the continuous use of an oral antiseptic by the patient, the composition of the preparation should be changed. Your committee recommends that Liquor Antisepticus should be omitted from future editions of the Pharmacopeia and that an improved preparation should be added to the National Formulary, where it rightly belongs.

Styptics: The surgical treatment of dental hemorrhage does not differ from that which occurs in any other accessible part of the body. Nevertheless, we meet with cases in which the use of styptics is indicated. For such purposes, cotarnin hydrochlorid (stypticin) and cotarnin phthalate (styptol) (see New and Nonofficial Remedies) have proven to be of good service. These remedies are certainly superior to any other styptic to be found in the present Pharmacopeia and either one of these compounds deserves to be recommended for admission to the U. S. P.

Antipyretics and Antineuralgics: Of the many compounds which have been advocated as antipyretics and antineuralgics, acetylsalicylic acid, known as aspirin (see Notes on New and Nonofficial Remedies) deserves to be recommended for admission to the U. S. P.

Analeptics: A useful restorative agent in cases of collapse, syncope, etc., is validol, either alone or as validol camphorate, *i. e.*, a solution of 10 per cent. camphor in validol. (See New and Nonofficial Remedies.) Its usefulness has been frequently tested and it deserves to be recommended for admission to the U. S. P.

PROPOSED CHANGES

Shorter titles or synonyms should be given to the following drugs: Acetphenetidin, hexamethylenamin, sulphonethylmethan and sulphonmethan.

Your committee further recommends the adoption of the following resolution by this Section:

> Whereas, the Section on Stomatology of the American Medical Association is taking special interest in the Revision of the Pharmacopeia of the United States, and.
>
> Whereas, at present no provision is made for representation of the dental profession of the United States in the United States Pharmacopeial Convention, therefore be it
>
> *Resolved*, that the Section of Stomatology of the American Medical Association should be entitled to one delegate who represents this body on the Committee of the Revision of the United States Pharmacopeia.

Respectfully submitted,
Hermann Prinz, Chairman.

Thyroid Administration in Children.—L. Williams, in the *British Journal of Children's Diseases*, June, 1909, states that as thyroid insufficiency is characterized by a subnormal temperature and sensations of chilliness, it might be expected that thyroid excess would be accompanied by a supernormal temperature and intolerance of heat; and such is the clinical fact. Experience has taught him when giving thyroid extract to children over considerable periods of time that the thermometer is as necessary a guide as the weighing machine. So long as the subnormal readings persist, the drug may be continued; as soon, however, as the temperature reaches normal, caution is necessary; and at the first indication of a rise beyond normal, the drug may be suspended.

Clinical Notes

STAPHYLOCOCCUS VACCINE IN INFLAMMATORY CONDITIONS OF THE GENITOURINARY ORGANS *

W. M. ROBERTSON, M.D.
ST. LOUIS

My attention was called to the staphylococcus vaccine by the following case:

Case 1.—*History.*—Mr. N. was referred to me in May, 1908, by Dr. M. B. Clopton. The patient was 18 years old, and had never had any venereal disease until the preceding November, when he contracted gonorrhea. From the time the disease first manifested itself, he had been treated by men both in St. Louis and New York City, who are well-known to be capable of treating such diseases. When I first saw him there was a profuse purulent discharge containing gonococci from the urethra; the first, second and third glasses of urine were so cloudy as to be termed milky; the prostate was enlarged, soft, sensitive on pressure and the expressed secretion contained only pus. There was present some frequency and urgency of urination.

Treatment.—I treated the patient for about three months according to the well recognized methods of treating such conditions, but met with no better success than had my colleagues who had previously treated him. So far as I could see there was absolutely no improvement in his condition, and I began to despair of being able to do anything for him. About this time he developed a suppurative folliculitis of the bearded portion of his face for the treatment of which he was referred to Dr. M. F. Engman. Ten days later, after having treated him to no avail for three months, and without any change in treatment, there was a marked improvement in his condition. In three weeks the urine was clear and in six weeks the patient was entirely well.

In speaking with Dr. Engman about the case, he told me that he had been giving the patient injections of staphylococcus vaccine. It then occurred to me that in these rebellious and obstinate infections of the prostate and bladder we have to deal, perhaps, with a staphylococcus and not a gonococcus infection; that while the gonococcus was the cause of the original infection after a time it lost its virulence and left to the staphylococcus the task of keeping up the disturbance which it had begun. This supposition was further strengthened by the fact that, while the gonococcus vaccine has been given an extensive trial in these conditions, few observers make for it any claim as a curative agent. Acting on this belief, I obtained staphylococcus vaccine to carry out my investigations.

At this time I had under treatment, or, more correctly speaking, under observation, at the genitourinary clinic of the Washington University the following patient:

Case 2.—*History.*—J. D., aged 20, laborer, contracted gonorrhea about one year ago, and was "cured" in four weeks. Three weeks ago, following some dissipation, but not having indulged in intercourse, the discharge again appeared. It became very profuse, but at the time when I saw him was slight and no gonococci could be found. Both glasses of urine were very cloudy; urination was frequent, painful, urgent and followed by much tenesmus. The prostate was much enlarged and painful and the secretion contained only pus. The patient was in destitute circumstances, his nights being spent in a box car or one of the city parks, and his meals were irregular and uncertain. His general condition was miserable, but on account of an ignorant prejudice he would not consent to go into a hospital.

Treatment.—I gave him the best treatment I could under the circumstances, but after two weeks his condition remained unchanged. I then began giving him hypodermic injections of staphylococcus (albus) vaccine, all other treatment being discontinued. The further progress of his case is as follows:

On August 29 and 31 and September 2 and 7 respectively 1 c.c. staphylococcus (albus) vaccine was given. At the end of this time the patient felt well, had no pain and no disturbance with urination. First glass of urine was cloudy, the second was clear, the prostate much diminished in size, and was not very painful on pressure.

On September 12 and 16 respectively 1 c.c. of staphylococcus (albus) was given. At that time he had no pain, no discharge, no disturbance with urination, both glasses of urine were clear, prostate was normal in size but the expressed secretion contained much pus.

On September 20 1 c.c. staphylococcus vaccine was again given.

On October 5 the patient had not returned for treatment as he had been feeling perfectly well. The urine was clear, the canal was free, the prostate normal in size, shape and consistency, and the expressed secretion was normal.

Case 3.—*History.*—E. D. first consulted me Oct. 15, 1908. He had contracted his first case of gonorrhea two months previously and on account of suppurative folliculitis had been in a hospital for two weeks. When I first saw him there was a slight discharge from the urethra containing gonococci; frequent urination, both glasses of urine being cloudy. The prostate was enlarged and the expressed secretion contained only pus. After having treated him for two weeks according to well-recognized methods of treating such diseases, his condition remained about the same. He then went away for a week and returned on November 7, complaining of pain in the right testicle and cord, pain in the back, frequent urination, in fact all the symptoms of impending epididymitis. He had to urinate every fifteen or thirty minutes and the urine was thick with pus. The prostate was enlarged and very sensitive.

Treatment.—I began the injections of staphylococcus vaccine, suspending all other treatment. After three injections, on November 7, 9 and 11 of 1 c.c. each, all of the subjective symptoms had disappeared. I then began prostatic massage and permanganate irrigations, injecting the staphylococcus vaccine every six days. This treatment was continued until December 21, when the patient was discharged cured.

Case 4.—*History.*—E. R. had had one attack of gonorrhea five years previously. On Oct. 28, 1908, two days after sexual and alcoholic dissipation, he developed acute prostatitis. Urination every ten or fifteen minutes, pain, urine very cloudy, prostate much enlarged and very sensitive. No discharge from the urethra.

Treatment.—I advised rest, hot sitz baths, opium and belladonna suppositories, and santal oil. This treatment was continued until November 7, with some relief, but the patient was still in great pain. I then discontinued this line of treatment and on November 7, 9 and 11 gave him 1 c.c. of staphylococcus vaccine. After the third injection all symptoms disappeared as if by magic. I then began prostatic massage and irrigations, giving the staphylococcus injections once a week. The expressed prostatic secretion was at first thick, yellow pus, but after continuing this treatment until December 21 it became almost normal and the patient has had no further trouble.

Case 5.—*History.*—F. D. first consulted me Jan. 4, 1909. He had contracted gonorrhea three weeks previously; first attack. When seen he had a profuse discharge containing gonococci, both glasses of urine cloudy, no disturbance with urination. He was treated by a hand injection of *protargol* and a preparation of santal oil. On January 23 he developed acute prostatitis. The prostate was enormously enlarged and very painful, urination every few minutes very painful and followed by much tenesmus. The discharge from the urethra had ceased.

Treatment.—Staphylococcus vaccine (1 c.c.) was administered, other treatment being discontinued. On January 25 1 c.c. staphylococcus vaccine was again injected. Condition about the same. Patient very uncomfortable. On January

---

* Read before the Medical Society of the City Hospital Alumni, June 3, 1909.

28 1 c.c. staphylococcus vaccine injected. Patient felt much better; second glass of urine almost clear; had little pain. On February 2 staphylococcus vaccine, 1 c.c. The patient was perfectly comfortable, *no pain, urination about normal.* First glass of urine was slightly cloudy, second clear; prostate much reduced in size. Prostatic massage and irrigations were then begun, the staphylococcus vaccine being injected every five days. In two weeks both glasses of urine were clear, and with the exception of some pus in the expressed prostatic discharge, the patient seemed entirely well. On February 25 he was discharged cured.

Case 6.—*History.*—Mc. E. contracted gonorrhea three years before he consulted me, Feb. 8, 1909. He had been subject to frequent recurrences of gonorrhea and occasional attacks of acute prostatitis. He was a traveling salesman and had a physician in almost every town in several states. I had treated him a year previous for three weeks for an aggravated case of acute prostatitis with only indifferent success. When he returned to me this time he was in about the same condition as when I first saw him. No discharge from the urethra, urination every few minutes and very painful, prostate enlarged, painful and very sensitive on pressure.

Treatment.—I gave him three injections of staphylococcus vaccine, 1 c.c. each, giving the injections every other day. Two days after the last injection, the urine was perfectly clear, the first glass only containing a few shreds. Urination was normal and the patient felt perfectly well. The prostate was much reduced in size and there was little pain on pressure. The patient then left St. Louis and I know nothing further of the progress of the case.

I could report many similar cases, but the record of cases becomes tedious and, to my mind, does not prove as much as does the opinion of the observer as to the efficacy of a certain remedy. I have used staphylococcus vaccine in twenty cases of acute prostatitis and cystitis in which there had been a history of gonorrheal infection dating back from a few weeks to many years, and have not yet met with a case in which the subjective symptoms have not been relieved after the third injection, these injections being given every other day. If continued every five or seven days, with other appropriate treatment, my cases have gone on to complete recovery with surprising rapidity. I have used these injections along with other treatment in cases in which the only symptoms were pus in the expressed prostatic secretion and recurrence of the urethral discharge following dissipation or sexual excesses. I am uncertain as to their efficacy in these cases, but my experience leads me to believe that they are worthy of further investigation.

I have used them in cases of lesions of the spinal cord and in cases of senile hypertrophy of the prostate in which either retained and decomposed urine, or instrumentation or both had caused troublesome bladder symptoms. In these cases where the infection was due to the staphylococcus, as it has been in many cases which have come under my observation, the result has been gratifying to both myself and the patient.

In one case of tabes of fifteen years' duration with an old chronic inflammation of the bladder, which I saw in consultation with Dr. Given Campbell, recurring chills followed by high temperature, the general condition of the patient, and the condition of the urine indicated an ascending suppurative renal affection. The improvement following the injections of the staphylococcus vaccine was so prompt and so marked that I am undecided whether to attribute it to the injections, to a mistaken diagnosis or to chance. At any rate, after having been confined to his bed most of the time for seven weeks and presenting at this time every symptom and indication of a marked septic condition, nine days after the first injection was given, the patient's condition was such that we felt justified in allowing him to undertake a European journey. After the first injection, there were no more chills, and no more fever, and at the end of a week there was a marked improvement in the condition of the urine.

I have used them in one case of incipient renal tuberculosis in a patient who, with Dr. C. Fisch, I am treating with tuberculin injections and in which there was a marked staphylococcus infection. The ordinary urinary antiseptics aggravated the condition and I began injections of the staphylococcus vaccine. In less than a month Dr. Fisch reported a marked improvement in the urine, but whether this was due to the staphylococcus or the tuberculin, or either, I do not know.

It is my custom to give the injections every other day for three injections. I then give them every five or seven days as long as they seem to be indicated. I have used only the *Staphylococcus albus,* using at each injection 1 c.c., which represents 400,000,000 bacteria. I have given several hundred injections. I have never had an abscess following them, nor have I had a patient complain of pain or any bad after-effects.

I hope that I am not overenthusiastic over the results which I have obtained by the use of staphylococcus vaccine. Acute inflammation occurring in cases in which an old gonorrheal infection existed may show the gonococcus or may not, but the staphylococcus is always present and, while the gonococcus was the original cause of the infection, I believe that after preparing the soil it lost its virulence and left to the staphylococcus the task of keeping up the mischief. It is in this class of cases only that I make an unqualified claim for the staphylococcus vaccine. In the other conditions in which I have used it, the small number of cases or other circumstances have prevented me from forming a positive opinion.

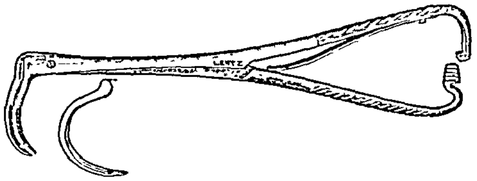
A LIGATURE-CARRIER

CHARLES B. REYNOLDS, M.D.
PHILADELPHIA

The ligature-carrier here illustrated I have devised for ligations of the broad ligaments and deep pelvic vessels especially. The instrument is nine inches long and composed of two pieces, with a deep curve, each containing one-half of the eye of the needle. The handle is large, of the ratchet type, and contains a strong spring.



A new ligature-carrier.

The ligature material is threaded through the eye of the needle, which is passed beneath the vessels or ligament to be ligated; the ligature is grasped with the fingers or forceps, the handle compressed and the halves of the needle forced apart by the spring and withdrawn. This obviates the difficulty of drawing the ligature through the eye, as in the old-style pedicle needle. Any ligature material may be used without danger of cutting it.

HAND CRUSHED: INFECTED WITH GAS BACILLUS OF MALIGNANT EDEMA

AMPUTATION OF FOREARM: RECOVERY *

G. PAUL LAROQUE, M.D.
RICHMOND, VA.

Were it not for the fact that the patient recovered from an infection which is alleged to be almost uniformly fatal, a single case report of an extremely rare infection would scarcely be worth while. On account of the fact, however, that patients infected by the so-called gas-producing bacillus of malignant edema nearly always die, even after the most radical and high amputations, a case of recovery following conservative treatment should be recorded.

Until the present case came under my observation I had seen only one case. This occurred in the practice of my former chief, Dr. Edward Martin, of Philadelphia. The patient was a young woman who suffered a compound fracture of the ankle and died within three days in spite of amputation at the hip joint. Another case occurred in the University Hospital in Philadelphia a short time before my period of service as resident surgeon in that institution, and this patient died in spite of high amputation. The following case is the only one I have heard of in Virginia in which the organism was demonstrated bacteriologically:

Injury.—R. C., a colored man, aged 32, while engaged in shucking corn with a machine on a farm about ten miles from Richmond, suffered a severe crushing of the left hand. He was at once referred by Dr. W. A. Campbell to Dr. Stuart McGuire's clinic at the Virginia Hospital. On examination of the injury by the resident surgeon, Dr. W. D. Carr, it was obvious that, on account of the extensive injury of the hand and wrist, amputation was indicated. I saw the patient about 8 p. m. of the day of admission. There was extensive mutilation of all the soft parts and bones of the hand and wrist and the tissues injured had already become black and obviously gangrenous. There was the characteristic gangrenous odor, and the hand and soft parts were infiltrated with gas to about two inches above the wrist. A diagnosis of gas-bacillus infection was at once made. A smear from the injured hand, examined microscopically by Dr. Guy Hopkins and Dr. G. H. Baerecke, showed the characteristic organism of malignant edema, together with some mixed infection.

Treatment.—Amputation of the middle of the forearm was at once performed by the resident surgeons, Drs. Carr and Booker, under my instruction. The next day the stump appeared black in color and a foul odor was emitted. Some of the bloody discharge from the stump was examined microscopically and the bacillus of malignant edema was found to be present. This caused us immediate alarm, and we at once took into consideration higher amputation. The patient's temperature was 103, pulse 120. In order to determine whether or not the infection was limited to the stump or whether it was being conveyed into the general circulation, we secured blood from the regional veins leading from the stump and also from the veins of the opposite elbow. Both of these specimens were submitted to the bacteriologists for examination, and in neither specimen was the organism present. Believing that consultation should always be held before any amputation is done, I called Dr. W. Lowndes Peple to see the patient. After discussing the matter for about half an hour, we concluded that, inasmuch as the patient's general condition was good and the local condition of the arm above the stump was good, higher amputation would not be justifiable. We therefore removed all the stitches and left the wound wide open to be treated with antiseptics and oxidizing agents, since it is a well-known fact that these organisms do not live in the presence of oxygen. Local applications of hydrogen peroxid, potassium permanganate and oil of turpentine were made to the raw surface and the stump enveloped with a dressing wet with 1 per cent. solution of chloral hydrate. The next day we made another examination of the blood leading from the stump and found it sterile. Two days later smears were made of the discharge from the stump and the bacillus of malignant edema was not to be found. The patient's condition remained good and recovery ensued as soon as could have been expected from a suppurating wound.

EXFOLIATIVE NEONATAL DERMATITIS

J. C. MATTHEWS, M.D.
SPRINGFIELD, MO.

The object in reporting this case, which might be termed dermatitis exfoliativa prenatal rather than neonatal, is to call attention to the undoubted development of this disease, or condition *in utero.*

Ritter, in 1878, was the first to call definite attention to this condition; but in all cases reported by him and others since that time I failed to find a case reported as existing at birth. From two to five weeks after birth is given as the usual time of development of symptoms.

Patient.—Baby R., male, was born at term, Feb. 8, 1909; normal labor; weight was 6½ pounds; the child was well-developed and seemingly of good vitality, as he breathed and cried well.

Condition at Birth.—When the arms and hands were delivered I noticed an unusual condition of hands, and on careful inspection of child, after delivery, I discovered that the hands and feet were denuded of epidermis. This condition included the fingers and toes, except their tips, and back to the wrists and ankles. The nose, penis and margin of umbilicus were also denuded, appearing dark red, not unlike a burn of the second degree caused by steam or hot water. The lesions were exuding serum as would a burn, and shreds of cuticle were hanging at the margins.

Treatment and Course of Disease.—The child was dressed and put to breast, which it nursed in a normal way. The raw surfaces were dressed with boric acid and sweet oil. On February 9 I saw the child in company with Dr. Anderson; we found it in a weakened condition, its face pinched and drawn, the clothing and bandages saturated with serum, and with some bleeding from the nose and margin of the umbilicus. We also found, on dressing it, that the exfoliation had extended up the arms and legs for from one to one and a half inches, and in pockets under the cuticle a clear serum similar to a blister caused by a burn was found. During the past twenty-four hours the child had nursed a little, bowels had acted, urine had been voided, and the child had cried a great deal. Temperature was 97 in the rectum.

February 10: The child was much weakened, it had not nursed since the last visit. The clothing and bandages were saturated and stiff with serum and blood; the surface of the body was cold, skin was pale and wrinkled; breathing was shallow. The heart sounds were weak, and attempts to cry produced only a weak moan.

During the night the child died. No postmortem examination was made.

History of Parents.—The mother was a decided blond, well developed, weight 118 pounds, age 18. This was her first child. Labor and recovery were normal. History of herself and parents was good, though she sunburns easily. The father is a medium blond, aged 21, healthy and hearty; weight 145 pounds. There is no history of syphilis or hereditary disease on either side.

Purity and Digestibility of Foods.—"The first requisite which we should make for foods for invalids is that they should be pure. The next most important thing is to find a pure food which the invalid can digest."—H. W. Wiley in the *New York Medical Journal.*

---

*Reported at the Richmond Academy of Medicine and Surgery, January, 1909.

Therapeutics

DIET IN TYPHOID FEVER

It seems almost impossible to settle this much discussed subject definitely, and it is doubtful if it ever will be determined that any one diet is the only correct one for typhoid fever. The patient, his dietary habit, and his ability to digest certain foods during typhoid fever must all be individualized. Therefore, a diet correct for one patient may be absolutely incorrect for another.

The recommended diets vary from nothing but water, or no diet, through absolute milk, entire absence of milk, liquid foods other than milk, cereal foods, to actual solid foods, including meat.

The diet in typhoid fever should never be discussed without due consideration of the management of the bowels. This means whether diarrhea should be allowed, whether laxatives should be given, or whether constipation should be caused.

In the first day or two of the fever the temperature is likely to be higher than it is on the days that immediately follow. This temperature is lowered, the tongue improved, and the patient made generally better by free purging, and a diet of little more than plenty of plain water. The purgative selected may be calomel, or may be castor oil administered in some pleasant form. Such a purgative may be repeated in two or three days if deemed advisable. There can be no question that a clean alimentary canal modifies greatly the severity of the early typhoid symptoms.

It has been lately shown that fecal deposits, seeds or other food débris may become lodged in the lower corner of the ascending colon, the cecum, and may cause inflammation or symptoms of appendicitis, and may even be a subsequent cause of appendicitis. Hence it may be found to be good treatment, in the first few days of typhoid fever, to give colon enemas of from one to two quarts of warm water, the patient lying on his right side, to aid in washing away the possible accumulations in the cecal region. Such colon washings can certainly do no harm in the first days of typhoid, and may be of marked benefit in the future course of the disease. In other words, the more thoroughly the pathologic process in the intestines, in typhoid fever, is considered from a surgical standpoint, with the aim to keep these ulcers and the inflamed intestinal mucosa as clean as possible, the less will there be secondary infection, the less will there be tympanites, the less will there be deep ulcerations, hemorrhages and perforations, the less high the fever, and the better the whole prognosis. Consequently, not only should the bowels be cleared at first, but subsequently the bowels should be moved daily. This is best done by administering every other day some gently acting saline laxative, which cleans the upper part of the intestines, tends to drain the portal circulation, to keep the liver, our Pasteur filter, in a healthy condition, and to cause an easy watery movement. Any tendency to a diarrheal condition or to too many movements from such a laxative may be stopped by the administration of 1/10 grain of morphin. The bowels are thus cleaned and subsequent excessive peristalsis inhibited, and the patient is generally at rest for the remainder of the day. On the alternate day a small glycerin enema, administered with a glass syringe, consisting of a tablespoonful of glycerin and a tablespoonful of water, will cause within ten minutes a movement of the bowels that will at least empty the descending colon and cause the expulsion of gas. Such management of the bowels seems contraindicated only by intestinal hemorrhage, signs of perforation and great prostration. Such treatment also prevents secondary infections that keep the temperature high. In other words, less antipyretic measures are needed, if the abdomen is flat, tympanites is not present, and the patient's bowels have moved daily artificially, and the movements are not caused by diarrhea due to irritation from the disease.

The fact should be emphasized that tympanites is not a symptom of typhoid fever, but is a symptom of mismanagement, a symptom of a mistake either in the diet or in the management of the bowels. Tympanites not being present, the danger from hemorrhage and perforation is reduced to a minimum. If the patient's bowels are properly managed in typhoid, tympanites will rarely occur.

As above stated, the exact diet that is best for the individual typhoid patient must be determined by his ability to digest, by the height of the temperature, by the behavior of the stomach (i. e., whether there is distress, nausea, or vomiting), by the amount of intestinal flatulence, and somewhat by the character of the stools. Any food, however advantageous theoretically, or however satisfactory for other patients, is contraindicated if it causes indigestion in any form, or is not digested. Theoretically, the food that causes the least mass of intestinal débris would be indicated on account of the less likelihood of food that is almost entirely digested in the upper alimentary tract forming a favorable medium and mechanical protection for pathogenic germs in the lower intestine. For this reason large amounts of milk would seem to be contraindicated, and certainly the all-milk diet is not the best for most patients who have typhoid fever. On the other hand, milk is too good, simple and generally well-digested a food for its use to be condemned in this disease. A solid diet as advocated by some, also, seems generally inadvisable. When it is considered that both high temperature and nervous disturbance caused by the disease, and also the general depression of the system, cause an interference with the production of normal gastric juice, food that requires normal conditions for digestion would seem to be contraindicated. Therefore, ordinarily a mixed diet representing the different elements of nutrition needed to protect the system against drain and loss and consequent unnecessary debility, the so-called typhoid state, and a diet that is varied sufficiently to prevent the patient from dreading the feeding hour is the one indicated. Any nutrient that is abhorrent to the patient should not be administered, as it is well understood that the digestive secretions are not produced so well when the patient dislikes, or is disgusted by, a food.

A good mixed diet for twenty-four hours, suitable for an ordinary adult ill with typhoid fever, is represented by one pint of milk; two eggs, or the whites of three eggs; one cup of thoroughly cooked, thin oatmeal gruel; the juice expressed from a pound of chopped, round steak; a small cup of coffee, in the morning; a small portion of wine, orange, or lemon jelly made from gelatin; and enough salt and sugar in the above to make them palatable.

The milk may be administered, hot or cold, with or without salt, with or without Vichy, with or without lime water, in two or three doses, as deemed best in the individual instance. Sometimes koumys makes a valuable substitute for ordinary milk. Sometimes buttermilk may be used, and this in larger quantities.

The eggs may be given raw, beat up with a little milk, or given with lemon juice on cracked ice, may be poached, or, if the temperature is not high, soft boiled or in the form of boiled custard.

The oatmeal gruel should generally be made with milk, and thoroughly cooked, strained, and salted to suit the taste.

Meat juice is best prepared by just covering the chopped steak with water, and allowing it to stand for an hour and a half. The water and juices are then expressed out of the meat. This watery extract will then contain, besides the blood of the meat, actual muscle serum, which is a decided tonic, especially to the heart. This expressed fluid is then kept on the ice and administered, properly salted, in two or three doses.

While gelatin is generally pleasant to most patients, it also has some nutritive value, and possibly tends to aid normal coagulation of the blood, and perhaps prevent capillary bleedings from the inflamed intestines.

A patient who is accustomed to his morning coffee need not be deprived of that pleasure because he has typhoid fever, unless there are meningeal symptoms, or meningitis is actually present.

If for any reason it seems inadvisable to administer meat juices to typhoid patients, and surely, if the patient is anemic, one or two doses of iron in the twenty-four hours should be given. The iron may be administered in five-drop doses of the tincture of the chlorid, in lemonade, once or twice in twenty-four hours; or a three-grain saccharated oxid of iron tablet (*Eisenzucker*) once or twice a day, or a capsule containing three grains of carbonate of iron, or reduced iron, may be administered once or twice a day.

The constant object in mind should be to administer protein (meat, eggs, milk), carbohydrate (oatmeal, sugars, or something similar), alcohol if deemed advisable, a mild cerebral stimulant (coffee or tea if thought advisable), iron, calcium (gelatin or lime water), sodium chlorid (perhaps dilute hydrochloric acid later), and water, enough of all to keep the physiologic processes as near normal as possible, while the patient is going through the long, tedious, feverish illness.

Experience seems to teach that it is best to administer nutriment to the typhoid patient in small amounts at three-hour intervals. It should, however, be arranged that the patient has normal rest. In other words, he should not be awakened from a comfortable sleep because it is time to do something to him or for him, and at regular three-hour feeding intervals should be the periods at which he is to be disturbed for other treatments. During the night, if he is not seriously ill, he should not be disturbed as often as every three hours.

With the treatment outlined, and with proper care of the mouth, the patient's tongue is rarely badly coated and should be moist, there should be no nausea, and there should be no tympanites.

The question that constantly arises in conjunction with the nutrition in typhoid fever is of what value are the so-called intestinal or bowel antiseptics. It is certain that the lower part of the small intestine can not be rendered aseptic. It is also just as certain that the stomach and a short distance at least of the small intestine may be made uninhabitable for pathogenic germs, without poisoning the patient. Perhaps the best stomach antiseptic is gastric juice, containing its normal amount of hydrochloric acid. If the hydrochloric acid is insufficient, pathologic germs may be present in the stomach, and certainly are likely to be present in the duodenum. Therefore, if it is considered in typhoid fever, at any period, that the hydrochloric acid is insufficient, a few drops of the dilute acid may be administered several times a day. If sodium chlorid is normally supplied to the patient, except possibly in the latter part of the fever, the hydrochloric acid is probably normally present, and except for the advantage of compelling the patient to drink more acidulated water, the necessity of administering hydrochloric acid is perhaps doubtful. Certainly a too acid stomach is not desirable.

Various preparations have been offered for intestinal antisepsis which contain an extra molecule of oxygen, or are really peroxid preparations. These are also taken with large quantities of water and probably do a great deal of good.

The best antiseptic to the upper part of the intestines seems to be salicylic acid in some form, and one of the best forms is the combination with phenol, viz., phenyl salicylate (salol), which may be given in capsules without any disturbance of the stomach, as it is there undissolved and breaks up into its component parts of salicylic acid and phenol in the duodenum. A small dose of this drug (0.25 gram or 4 grains) every six hours may be given continuously through the disease, unless there is a diminished excretion of urine, or albuminuria develops, or the urine shows darkening from the phenol, which would be very rare from this sized dose. Even the non-believers in bowel antiseptics must admit that whether the colon bacilli or typhoid bacilli come to the upper part of the intestine by migration, or reach these regions through the blood stream, that it would not be so healthy for them provided salicylic acid was present in the upper intestine as though it were not present.

How good a bowel antiseptic hexamethylenamin (urotropin) is has not been determined, but in post-typhoid conditions when typhoid bacilli or colon bacilli may be present in the pelvis of the kidney or may be present in the gall bladder, it has been shown that administration of hexamethylenamin is the best treatment to prevent their remaining permanently and causing inflammation in these regions.

Thus far sour milk treatments, lactic acid germs and the administration of yeast have not been mentioned. Certainly bowel infections of most kinds are made better by the administration of yeast. The value of sour milk treatments in typhoid fever must be determined by experience. A patient, however, who is not doing well on the diet above suggested should be put on the sour milk treatment. One of the principal objections to such treatment is that the patient's stomach soon objects to any one diet that is to be long continued, although for a few days he might accept the soured milk. On the other hand, most patients do not object to the sour drink produced either by a tablespoonful of upper brewer's yeast in a glass of water, or by the solution of a five-eighths inch cube of a compressed yeast cake in a glass of water, given two or three times a day.

Portable Shower Baths.—A simple way of providing shower baths for the multitude has been in operation in Baltimore. On open lots tents were divided by cloth into sections for towel-room, waiting-room, dressing-room, and several bath compartments. There was a wooden floor and a wood frame carrying water-pipes and shower-heads with regulating valves within the reach of the bather. Drainage was provided to the street gutter. This outfit cost about $150. It could be maintained for $25 a week, including two men attendants. Later, portable wooden bath houses covered with galvanized iron were used, and hot water supplied from a small coal stove with a water jacket and a tank.

USING THE DAYLIGHT

Human nature has a curious tendency, once started in a wrong direction, to continue by inertia until something untoward turns up to modify the tendency or until some definite movement is organized to prevent further progress that may be serious. There are many illustrations of this principle, though perhaps the well-known tendency of the so-called middle C of the musical scale furnishes the best known example. Theoretically this should have 256 double vibrations a second. Instruments were gradually tuned higher and higher, however, making it more and more difficult for the human voice to reach notes that had been reached with comparative ease before, until a definite movement was organized to prevent further heightening and even then the tendency was not entirely overcome. We are in something of the same condition of affairs as regards light as is thus illustrated in sound. When illumination was poor, people went to bed shortly after nightfall and arose at daybreak. As illumination has become better, they have gone to bed later and later, especially in the cities; and the hour of rising has grown later until, in the summer at least, many persons sleep as much during daylight as in the dark.

This is of course unfortunate. Sleep is never so restful—at least for most persons—during the hours of light as when it is dark. Everyone knows this from personal experience. The old saw was that two hours of sleep before midnight were worth twice that amount afterward; and while this may not be literally true, the truth in it is that if sufficient sleep is to be obtained after midnight, then much of it must be secured after darkness has ceased when sleep is not so beneficial. Everywhere one hears the complaint that people are becoming more nervous and are losing the power to rest thoroughly. Undoubtedly, some of this—probably much more than we suspect—is due to the fact that so much of sleep in city life where the increase in nervousness is particularly noticeable must under present conditions be obtained during hours of daylight. Even though most individuals do not get up, some of the workers must be about their duties, so that while the sleeper's eyes are disturbed by light, his ears are vexed by noises; and, though the light and sounds may not actually wake him, yet they make sleep a much less complete refreshment of tired organs.

There is excellent reason, then, for welcoming the movement of the National Daylight Association, which is endeavoring to secure, as we have noted[1], more daylight for work and more of the night for sleep. A practical method for the first step in this direction is outlined in the bill introduced into the British parliament, which proposes to set all the clocks of the kingdom forward an hour in May and to change back again in October.[2] A similar bill, as we have said,[1] is before the Canadian parliament and seems likely to become a law. The movement has attracted much less attention in this country, but it is needed here above all. Some time ago we deprecated the foundation of a day-and-night bank, open every hour of the twenty-four, because this made a definite precedent for the extension of business hours beyond the legitimate time. Men may apparently accomplish more work by crowding some hours of the night with it, but they draw drafts on time that are sure to be presented by Nature, often with no days of grace; and in the end it is probable that their actual capacity for business is shortened.

There are many reasons besides those that we have suggested why physicians should interest themselves in the new movement. Undoubtedly the ever-lengthening use of eyes under artificial light is the main cause for the growing number of people who must use spectacles at ever-earlier years. While a definite effort is still made in cities to send children to bed early, this is not nearly so successful as it used to be, and bedtime for them is advancing as for adults. This is one reason why more city children need spectacles and nerve tonics, for their sleep is even more likely to be disturbed by the light in the morning than that of their elders. In a word, we have very probably in this movement for prolonging the usefulness of daylight one of the most important hygienic ameliorations that can now be made for all classes of people. Doubtless the working classes would benefit even more than most others, because, while their fatigue requires them to go to bed early, the activity of life around them often seriously disturbs their sleep during the hours before midnight which should be so precious. Let us hope that so simple and efficient a means of lessening one of the unhygienic tendencies of our day will receive the consideration it deserves.

HEXAMETHYLENAMIN AS A PROPHYLACTIC

The knowledge that the gall-bladder may become a habitat for *B. typhosus* and account for "chronic bacillus-carriers" has stimulated considerable search for a drug which will disinfect the biliary passages. Studies of Mosler, Meder, and Vieillard have shown that certain substances like potassium iodid, sodium salicylate, and mercuric chlorid are excreted in the bile, but none is excreted in concentration sufficient to be serviceable.

[1] THE JOURNAL A. M. A., July 31, 1909, lii, 383, 387.

[2] THE JOURNAL A. M. A., July 25, 1908, li, 324, 328.

Crowe, in 1908, chose hexamethylenamin for his experiments because (1) of its known effect on typhoid bacilluria (Richardson; Churchman) and (2) of its easy recognition. Crowe's experiments on dogs showed that the drug, administered by mouth, was rapidly absorbed and remained in the circulating blood in recoverable amounts for twenty-four hours. He found it in the bile, secreted not only by the liver, but also, in even larger amounts, by the way of the gall-bladder itself.

Applying these results therapeutically in a number of human cases of postoperative biliary fistulas, he determined by careful bacteriologic and chemical study that, if the dose by mouth be large enough (75 grains per diem), the bile is rendered sufficiently antiseptic to inhibit the growth of bacteria. He then recommended its use (1) in acute infection of the gall-bladder, (2) as a prophylactic before gall-bladder operations, and (3) to lessen the occurrence of gallstones and also of chronic bacillus carriers after typhoid fever.

During his work Crowe demonstrated the presence of the drug in the bile, synovial fluid, saliva, pleural fluid, circulating blood, and cerebrospinal fluid in man after administration by mouth. Recently (1909) he has published the results of a series of experiments attempting to overcome artificial meningeal infections by hexamethylenamin. In forty experimental observations the animals received the drug before infection. Many survived, and the others lived longer than animals receiving it after inoculation, and much longer than the controls to which the drug had not been given.

In man he found the hexamethylenamin present in amounts sufficient markedly to inhibit the growth of organisms inoculated in the cerebrospinal fluid removed by lumbar puncture. In one case purulent meningitis from an infected cerebrospinal fistula cleared up under its use.

Apparently Crowe has thus shown that hexamethylenamin will do also for the cerebrospinal fluid what it has been known to do for the urine. He recommends its administration (1) in cases of fracture of the skull, (2) in cases of gunshot wounds of the head, (3) as a preliminary to ventricular and lumbar puncture and to spinal and cerebral operations, and (4) in cases of extracranial infections where extension to the meninges is feared, as in otitis media and suppurations of the sinuses. Should it prove as preventive as is hoped it will be a boon to the ear and nose specialist and a most important advance will have been made in the field of prophylactic therapeutics.

A POISONOUS HAIR DYE

On another page[1] in this issue we record three more cases of poisoning from the use of a preparation known as Mrs. Potter's Walnut Juice Hair Stain. This makes eight cases that have been reported to THE JOURNAL within the past six months. It would seem that the time is about ripe for some action to be taken either by state or federal authorities to limit or prevent the further sale of a preparation which has proved dangerous. According to the chemists of the North Dakota Agricultural Experiment Station, this hair dye depends for its action on paraphenylene diamin, a substance which when oxidized by means of a solution of hydrogen dioxid becomes an intense black. The poisonous qualities of this substance have been long known. Eighteen cases of poisoning have been recorded by Cathelineau,[2] who has reported somewhat exhaustively on the subject. Its physiologic effects have been studied by Laborde and Mellière[3] and also by Dubois and Vigum.[4] Hypodermatically administered to dogs, it produces tenesmus, diarrhea and salivation, followed by lowered temperature, opisthotonos and death in from ten to twenty hours. In Mellière's patient the urine was mahogany-colored, though apparently this effect is not always produced. The dermatitis caused by paraphenylene diamin is not always a light attack. L. Brocq[5] described a severe form in which the glands are affected, there is high fever, with a violent eruption and extensive desquamation. A case of poisoning has been reported by Balzer[6] due to wearing hose which had been dyed with the chlorate of paraphenylene diamin. A case of dermatitis from the use of a hair dye having as its base the hydrochlorate of paraphenylene diamin was reported at some length by A. D. Mewborn,[7] who gave a bibliography of cases of poisoning due to the drug and described at some length the preparation, reaction and method of use. The dangerous character of this chemical should in itself be a sufficient reason for controlling its indiscriminate sale to the laity. If Mrs. Potter's Walnut Juice Hair Stain depends for its action on paraphenylene diamin instead of on walnut juice, this fact alone plainly constitutes misbranding within the meaning of the national Food and Drugs Act. To the advertisements of the preparation which state that it "contains no poisonous dyes" the eight cases reported in THE JOURNAL give the "lie direct."

RECONSTRUCTION OF THE BILE DUCTS

Dr. Sullivan's article in this issue giving an account of the ingenious operation which he has contrived and of which he has experimentally demonstrated the feasibility, seems worthy of some special notice. The utilization of the peristaltic tug in the intestines to remove by that route the foreign body, the rubber tube used in restoring the bile passage, is a novelty. Should the further observations on the experimental animals prove that it is not followed by any serious symptoms or complications it may be recommended for practical use in suitable cases in the human subject. The dangers as they appear to us would be in properly securing against leakage in the peritoneal investment, or the too premature expulsion of the rubber tube before the tissues of the new channel have become properly adapted to their new function. These risks, however, seem to be negligible ones in the dog and, so far as purely experimental methods can be trusted, the operation seems likely to be a success. Whether the principle of attaching a sponge and using the peristaltic action of the intestines to complete the operation for internal drainage has any wider application or not does not matter—it appears certainly to be an advance in the surgery of the biliary tracts. As Dr. Sullivan says, the other steps in the operation are more or less already accepted details.

Medical News

CALIFORNIA

A Case of Bubonic Plague.—The first case of bubonic plague to be discovered in the state for a year was discovered in Alameda county August 6. The patient, a boy of 13, is supposed to have contracted the disease through handling infected squirrels killed by him on a hunting trip. In consequence of this case, there is renewed activity in the campaign of extermination against the ground squirrel.

Personal.—Dr. Charles C. Stephenson, formerly secretary and president of the Arkansas Medical Society, and professor of ophthalmology and otology in the College of Physicians and Surgeons, has left Little Rock on account of ill-health and located in Los Angeles.——The degree of LL.D. has been conferred on Dr. Francis M. Pottenger, Monrovia, by his alma mater, Otterbein University of Westerville, Ohio.——Dr. George H. Fay, East Auburn, has been appointed local surgeon for the Southern Pacific Railway.——Dr. Lulu H. Peters has been placed in charge of the pathologic work at the Los Angeles County Hospital.——Dr. Antoinette M. Bennette, San Bernardino, has accepted the position of resident physician and superintendent of nurses at the San Bernardino County Hospital.——Dr. Philip V. K. Johnson, city physician of Los Angeles, has resigned.——Dr. Gustave Wilson, first assistant physician of the Southern California Hospital for the Insane, Patton, has resigned.——Dr. David Gochenauer, San Diego, who has served as general manager of the Angelus Hospital, Los Angeles, for a year and a half, has returned to his home in San Diego.——Dr. Charles F. Wade, Los Banos, is reported to be critically ill.——Dr. Wallace I. Terry, chief surgeon of the San Francisco Emergency Hospital Service, announces that he will resign in October.——Dr. J. B. Rogers has been appointed a member of the Alameda Board of Health.

DISTRICT OF COLUMBIA

Personal.—The Cross of the Legion of Honor has been conferred by the French government on Dr. Harvey W. Wiley, chief of the bureau of chemistry.——Dr. G. Lloyd Magruder is the representative of the departments of state and agriculture at the International Medical Congress, Budapest.

ILLINOIS

Personal.—Dr. Lewis A. McFadden, Peoria, who was operated on recently in St. Francis' Hospital for intestinal obstruction, is reported to be improving.——Dr. Edward Hasson, Peoria, was operated on for appendicitis, August 10, at the Proctor Hospital.——Dr. Charles W. Gould, Fairdale, has started for the west and will later go abroad.——Dr. John M. Phifer, Stewardson, has been appointed assistant surgeon of the Atchison, Topeka and Santa Fe Hospital, Topeka, Kan.——Dr. Henry M. Bascom, Ottawa, has been appointed chief surgeon of the Illinois Traction System and of the hospital association of that system.——Dr. Olof Nordvall, Rockford, has returned from Europe.——Dr. Daniel W. Gross, Watseka, has been made a member of the Iroquois county board of U. S. pension examining surgeons, vice Dr. Robert Lumley, deceased.——Dr. and Mrs. R. Jay Atwood, Paxton, sailed for Europe August 11.——Dr. W. E. Taylor, superintendent of the Watertown State Hospital, has been granted six months' leave, becoming effective August 1.

Chicago

Day Nursery Opened.—The Clara Palmer Goetzinger Free Day Nursery of the Esther Falkenstein Settlement House, which will accommodate more than 100 babies, was opened August 16.

Outdoor School.—The first week of the operation of the Outdoor School for Tuberculosis Children showed gratifying results. About thirty of the children of the stock-yards district availed themselves of the opportunity, and they not only derived physical benefit, but obtained ideas regarding hygiene which should benefit them after the closure of the school.

Milk Examination.—During the week ended August 28, bacteriologic examination was made by the health department laboratory of 144 samples of milk and ice cream. The average bacteria count of raw milk was 6,660,290, and of pasteurized milk 378,300; in other words, the raw milk contained 139,600 more bacteria to the drop than the pasteurized milk. The ice cream averaged 10.537,915 bacteria to the cubic centimeter.

Medical Research Institution Founded.—The widow of Nelson Morris has given $250,000 for the erection and complete furnishing of the Nelson Morris Memorial Institution of Medical Research, to be connected with Michael Reese Hospital. The building will be constructed according to the ideas of Dr. James W. Jobling, pathologist of the hospital, and recently pathologist at the Rockefeller Institute. He will also direct the scientific work of the institution.

Personal.—Dr. Anton J. Carlson has been appointed associate professor of physiology, and Dr. H. Gideon Wells, assistant professor of pathology in the University of Chicago.——Dr. and Mrs. Fenton B. Turck and Dr. Louis L. McArthur have gone abroad.——Dr. G. N. Wassom has moved to Oelwein, Iowa, and has been appointed local surgeon for the Chicago Great Western Railroad.——Dr. Truman W. Brophy fell in his room in Berlin, August 19, and sustained painful injuries.

MARYLAND

Personal.—Drs. William J. Todd, Mount Washington, L. Gibbons Smart, Lutherville, and J. H. Jarrett, Towson, have been appointed censors of the Baltimore County Medical Association.——Dr. Henry L. Naylor, Pikesville, has been appointed a member of the State Commission on Pure Food, and on the subcommittee to draft a pure food law.

Prevention of Ophthalmia of the Newborn.—Mrs. Joseph Colt Bloodgood, Baltimore, secretary of the new Maryland Society for the Prevention of Blindness, has issued a circular which has been sent to all physicians in the state, asking them to pledge themselves to use some approved method of prophylaxis of ophthalmia neonatorum in their obstetric practice. The circular states that one-fourth of the blindness of children and one-eighth of all blindness is due to ophthalmia neonatorum.

Baltimore

Death from Pellagra.—A woman, aged 52, from Washington, D. C., died at Mercy Hospital, Baltimore, August 21, from pellagra. This is the third case of the disease observed in Maryland.

Cholera Ship on the Way.—Considerable anxiety exists in health circles over the announcement that the steamer *Andyk* from Rotterdam, a port infected with cholera, sailed for Baltimore August 25, and is due September 8. So far as known no case of cholera existed on the ship at the time of leaving port.

New Wards.—A new ward to cost about $140,000 is to be constructed at Bayview Asylum. It will be four stories in height, constructed of brick and re-enforced concrete, will be fireproof, and will contain a gymnasium and dormitory.——A new building is to be erected by the Church Home and Infirmary for a nurses' home and ward for children, at a cost of about $25,000. The building will accommodate from forty to fifty nurses.

Personal.—Dr. Percy M. Dawson, associate professor of physiology in Johns Hopkins Medical School, has resigned to take up the study of theology.——Dr. E. A. Erlanger has been made associate professor of physiology and Dr. C. D. English has been promoted to fill the vacancy caused by Dr. Erlanger's promotion.——Dr. Thomas C. Worthington has sailed for Europe.——Dr. John Doyle, interne at Mercy Hospital, was operated on for appendicitis at that institution, August 18.

MASSACHUSETTS

Personal.—Dr. and Mrs. Richard C. Cabot, Boston, have sailed for Scotland.——Dr. Samuel A. Green, formerly mayor of Boston, was overcome by the heat, August 9, and fell and sprained his ankle.

Tuberculosis Camp Opened.—Prendergast Tuberculosis Camp at Mattapan opened August 6, for the reception of patients. The camp comprises twenty acres, on which has been erected a large one-story wooden building, equipped with electric lights shower bath, dormitory and refectory, accommodating 12 men and 20 children. The children stay at the camp during the day, and the sleeping accommodations are for former sanatorium patients who have been discharged as cured, but wish to continue the open-air treatment. Once a week the children are sent to the Boston City Dispensary for examination.

MICHIGAN

Peninsula Physicians Meet.—At the annual session of the Upper Peninsula Medical Society, held in Calumet August 4, Sault Ste. Marie was selected as the next place of meeting, and the following officers were elected: President, Dr. Edward T. Abrams, Dollar Bay; and vice-presidents, Drs. Robert B. Binnie, Sault Ste. Marie, and John MacRae, Calumet.

State Society Meeting.—The Michigan State Medical Society will hold its annual meeting at Kalamazoo, September 15 and 16. The Kalamazoo Academy of Medicine will act as host of the organization. The general meetings will be held in the Congregational church, and the house of delegates will hold its session in the rooms of the Academy of Medicine. Dr. Archibald Church, Chicago, will deliver an address on "Mind Cures in General and Emmanuelism in Particular."

MISSOURI

Demands Clean Cars.—Governor Hadley has sent a letter to Dr. Albert H. Hamel, St. Louis, president of the State Board of Health, requesting that the board confer with the general managers of the railways in the state for the purpose of obtaining compliance with such sanitary regulations as he deems it advisable to adopt.

Personal.—Dr. Wilson J. Ferguson, Sedalia, has been appointed examining physician for Pettis county for the Missouri State Sanatorium.——Dr. Frank B. Hiller, Kahoka, has been elected secretary of the State Board of Health, vice Dr. James A. B. Adcock, Warrensburg, resigned.——Dr. John A. Riley, Fulton, has been appointed first assistant physician of the State Hospital, Patton, Cal.——Dr. William J. Calvert, Columbia, has been appointed professor of medicine in the Baylor University College of Medicine, Dallas, Texas.

NORTH CAROLINA

Personal.—Dr. John T. Battle, Greensboro, who was operated on for appendicitis at St. Leo's Hospital, is making a good recovery.——Dr. Chalmers M. Van Poole, Craven, has been elected president of the Rowan Farmers' Mutual Insurance Company.——Dr. Andrew W. Goodwin, Raleigh, who was recently suspended from the Wake County Medical Society, has resigned as professor of diseases of the skin and of the genito-urinary system in the University of North Carolina Medical School, and also as professor and demonstrator of anatomy in the Leonard Medical College in the same city.——Dr. Henry B. Marriott, Battleboro, has been appointed director of the State Hospital for the Insane, Raleigh, vice Dr. William H. Whitehead, Rocky Mount, deceased.——Dr. William W. Stancell, Margarettville, has been elected assistant physician at the State Hospital for the Insane, Raleigh, vice Dr. Charles L. Jenkins, Raleigh, transferred as physician in charge of the epileptic group or colony building.——Dr. William J. McAnally, High Point, is seriously ill from the bite of a poisonous spider.

NEW YORK

Personal.—In the recent fire at Monticello the home of Dr. John F. Curlette was entirely destroyed.——Dr. Nathan E. Beardsley, Dunkirk, was seriously injured in an automobile accident recently.——Dr. A. C. Kniskern has been elected president of the board of education of Mechanicsville, vice Dr. Walter C. Crombie.

Objections to Water Pollution.—Dr. Eugene H. Porter, State Commissioner of Health, announces that there are three reasons why there should be no pollution of the state's natural water courses—the protection of public health, the prevention of public nuisances and the safeguarding of riparian rights. In general, he is of the opinion that the greatest damage to riparian rights and the most widely felt interference with the use of streams for manufacturing and agricultural purposes results from the discharge of untreated industrial waste rather than from the discharge of domestic sewage.

Tuberculosis Campaign Bringing Results.—The war against tuberculosis in New York State is beginning to show results. ——Dr. E. H. Porter, State Commissioner of Health, has authorized the establishment of a camp at East Bloomfield, Ontario county.——Rochester is to have a city hospital.——Yonkers is doing creditable work for its tuberculous.——Ontario county has made an appropriation for a tuberculosis hospital.——Ex-Governor Odell has endowed a hospital for Orange county at Newburgh and Elmira has received a similar donation from Mr. and Mrs. Rapelyea.——Poughkeepsie has a model day and night tuberculosis camp.——Buffalo and Rochester have also made special provisions for the care of their tuberculosis patients.——The Woman's Antituberculosis League of Albany has planned for a "Button Day" on Labor Day, September 6.

Sanitary Conditions of Summer Resorts.—The sanitary inspection of summer resorts, which was first taken up by the State Department of Health in 1906, has been continued. In the Long Island district, five out of twenty-seven resorts were found to be in insanitary condition. At the reinspection last year, conditions had been corrected in two instances, and at the second inspection in June, 1909, the insanitary condition had been removed in one instance and partially removed in a second, while at the third, sanitary work was being carried on. In the Catskill resorts, nineteen out of sixty-four were found to be in insanitary condition, and at the 1908 reinspection, twelve were found to have corrected the nuisance, while at the reinspection in June, 1909, two of the remaining seven have made improvements, and the proprietors of the remaining five promised to make the desired changes in sanitary arrangements. In the Raquette River and Saranac and St. Regis watersheds, forty-two resorts were inspected, in twenty-four of which insanitary conditions were found to exist.

New York City

Inspectors Dropped.—Notices were sent August 20, to thirty-three medical inspectors who were appointed February 25, that their services would be dispensed with after August 25.

Personal.—Dr. Alpheus Freeman sailed for Europe August 28.——At the semi-milennial anniversary of the University of Leipzig, the degree of doctor of medicine was conferred on Prof. E. B. Wilson.——Dr. J. Richard Kevin, Brooklyn, has succeeded Major Henry L. Cochran as surgeon of the Twenty-third Infantry, N. G. N. Y.

Hospital Improvements.—Plans have been filed for a nine-story annex to the Babies' Hospital at Lexington avenue and Fifty-ninth street, which will cost $50,000.——Plans have also been filed for a new private laboratory for the professors of the College of Physicians and Surgeons of Columbia University to be built on the roof of a corridor connecting two wings of the college. This improvement will cost $3,000.

Epidemic of Paralysis.—In the Brownsville section of Brooklyn an epidemic of infantile paralysis has broken out which has afflicted more than 200 children between the ages of 1 and 5 years. Physicians and parents charge the Health Department with laxity as it is claimed that cases were reported two weeks ago and no measures were taken to investigate the nature and causes of the epidemic.

Academy News.—The Wesley M. Carpenter Lecture of the New York Academy of Medicine for 1909 will be delivered October 21, at 8:30 p. m., by Dr. Howard T. Ricketts, professor of pathology in the University of Chicago, on "Some Aspects of Rocky Mountain Spotted (Tick) Fever, as Shown by Recent Investigation." On November 18, the anniversary address will be delivered by Dr. Louis Livingston Seaman on "Personal Observations of the Sleeping Sickness in Central Africa."

Holmes Centenary.—The county medical society, on October 9, will hold a meeting commemorative of the eminence as a physician of Dr. Oliver Wendell Holmes. The meeting will be held at the New York Academy of Medicine, and addresses will be made by Dr. Maurice H. Richardson of Harvard Medical School on "Personal Reminiscences of Dr. Oliver Wendell Holmes," by Dr. Edward O. Otis, Boston, on "Dr. Holmes' Achievements as a Physician," and by Dr. William H. Thomson, New York City, on "The Many-Sided Holmes."

City Children and Tuberculosis.—An investigation made during the summer at the Sea Breeze Hospital, maintained by the Association for Improving the Condition of the Poor, indicates that from 25 to 30 per cent. of the small school children in the poorer tenement districts of the city are infected with tuberculosis. Up to the middle of August 728 children had been tested for tuberculosis at Sea Breeze, 381 boys and 347 girls. Of this number 205 and 281 respectively showed a positive reaction to the tuberculin test. The percentage of reaction among the girls was much higher than among the boys. The reaction in many instances may have meant only a tuberculous gland which would probably lead to nothing serious.

PENNSYLVANIA

Farmers and Tuberculosis.—At the farmers' meeting at Landenberg, August 27, 5,000 people were in attendance. The important phase of the gathering was the launching of the antituberculosis campaign for pure milk. The meeting was addressed by dairymen, physicians and educators from various parts of the country.

Fight on Witchcraft.—"Hex" and "Pow-Wow" physicians, who have had a strong hold on the superstitious portion of the population of Reading and surrounding country for many years, and who are said to be responsible for the deaths of six infants, are to be prevented from doing business by the health authorities. The coroner of Berks county is using every effort to bring the guilty persons to justice.

Personal.—Mr. Wallace Hatch, executive secretary of the Pennsylvania Society for the Prevention of Tuberculosis, has resigned.——Dr. William J. Davidson, physician at the plant of the Pressed Steel Car Company, McKee's Rocks, was wounded severely in the neck and arm during the riots, August 22.——Dr. John Hoskins, Chester, was thrown from his carriage, August 22, and seriously injured.——Dr. Albert Ellershaw, Bridgeport, has sailed for Europe.

Medical Missionary Society.—Application has been made for the incorporation of the Pennsylvania Medical Missionary Society with the objects of assisting students of evangelical faith, preparing for medical missionary work; of diffusing knowledge and arousing interest in medical missions; of obtaining contributions of money for their support; and of establishing and maintaining homes or residences for the use of missionaries and students preparing for missionary work.

Philadelphia

Personal.—Dr. Walter W. Roach has been appointed assistant medical inspector in the bureau of health, vice Dr. William Drayton, Jr., resigned.——Dr. John L. Borsch, Jr., has been decorated by the Italian government for professional services rendered the king of Italy.——Dr. Charles F. W. Plass has returned from Europe.——Dr. Mortimer Herzberg, assistant bacteriologist to the bureau of health, has resigned to accept the professorship of pathology and bacteriology in the University of South Dakota.——Dr. Charles S. Barnes has sailed for Europe.

Bags for Milk.—The director of health and charities, on August 20, began the distribution of bags, in which it is proposed milk dealers shall place the supply of bottled milk served to customers. The bags, besides protecting the food supply, have printed on them advice regarding pure milk, which is as follows:

> Buy milk from a RELIABLE DEALER, where you get it clean and fresh.
>
> Keep the milk ALWAYS on ice. Don't leave it standing for several hours on the doorstep.
>
> Keep bottles and every utensil coming in contact with milk ABSOLUTELY CLEAN.
>
> Feed at regular intervals. Keep baby clean. Bathe every day. Keep rooms clean.
>
> Keep child in shade and in open air as much as possible.
>
> If you obtain milk in bottle (the best way) allow it to stand on ice for a few hours before making the day's feeding. Shake the bottle before using. If obtained in can or pitcher, COVER it to prevent dirt from entering.
>
> If the milk mixture does not agree with the baby, try for one or two days, removing one-half the quantity of boiled water and in its place add the same quantity of BARLEY WATER (made by boiling one tablespoonful of pearl barley in one quart of water for one hour, and then straining).
>
> If the child vomits, has loose, green passages, or is otherwise sick, procure medical aid, without delay.
>
> At all ages between feeding give freely to the baby water previously boiled.
>
> Do not give any other liquids or any solid food, except on advice from a physician.
>
> For detailed information apply or write to the Bureau oof Health, Room 712, City Hall.

VIRGINIA

Typhoid Study.—The Virginia Department of Health has announced that Staunton will be the center of the new movement for the study of the typhoid fever situation in the valley. A traveling laboratory will be established in charge of Dr. A. P. Waddill, under the supervision of Assistant Health Commissioner A. W. Freeman and Dr. H. T. Marshall.

Personal.—Dr. John R. Bagby, health officer of Newport News, has resigned.——Dr. J. Frazer Jones, Richmond, was operated on for appendicitis, August 9.——Dr. W. L. Statewood has succeeded Dr. T. F. Jarrett, resigned, as assistant physician at the Central State Hospital, Petersburg. Dr. Thomas W. M. Long has been appointed second assistant physician, Dr. James C. Bardin, pathologist and bacteriologist, and Drs. Meade S. Brent, Northumberland county, and Robert A. Davis, Newport News, have been appointed additional assistants.——Dr. Lawrence T. Royster has been elected chairman of the school board of Norfolk.

GENERAL NEWS AND COMMENT

Obstetricians to Meet.—The annual meeting of the American Association of Obstetricians and Gynecologists will be held in the Hotel Anthony, Fort Wayne, Ind., September 21-23, under the presidency of Dr. William H. Humiston, Cleveland, Ohio.

Guarding Against Bubonic Plague.—To guard against the introduction of bubonic plague in United States ports, the Public Health and Marine-Hospital Service has directed its surgeons at leading shipping ports to enforce the rules safeguarding vessels bound for American ports against infection by rats. In eastern ports, vessels bound for America are not allowed to go alongside wharves, and are required to have rat guards on all lines before bills of health are furnished them.

Personal.—Surgeon Henry R. Carter, P. H. and M.-H. Service, director of hospitals of the Canal Zone, and family, sailed from Cristobal for New York, August 11. Dr. Carter has had more than five years' service in the isthmus and will not return at the expiration of his leave of absence.——P. A. Surgeon Donald H. Currie, P. H. and M.-H. Service, has gone to Bergen, Norway, as a delegate to the International Leprosy Congress.——Surgeon-General George H. Torney and Major Paul F. Straub, Medical Corps, U. S. Army, are representing the Army at the International Medical Congress, Budapest. During General Torney's absence, Col. Valery Havard will act as Surgeon-General.——Dr. Duke W. Goodman, U. S. P. H. and M.-H. Service, Fort Limon, is reported to be seriously ill with cerebral hemorrhage.

Army Instructs National Guard.—The Medical Corps of the Army has made experiments this summer in establishing camps of instruction for the medical department and hospital corps of the national guard of the various states. These three camps were established at Antietam, Md., Sparta, Wis., and the Presidio of San Francisco, under the charge of officers of high rank in the medical corps of the army, and were kept open for two periods of fourteen days each. The officers attending the camp were furnished pay, transportation, and subsistence, and the work undertaken included hospital corps drill, first-aid work, military hygiene, medical service in campaign, administration, and practical field work. Great interest was taken in the course of instruction by the students and it is to be hoped that the government will see fit to continue this excellent and valuable work.

Warning Concerning Alleged Agent.—The profession is warned against a man who pretends to represent the William Meyer Company, manufacturers of electrotherapeutic apparatus, Chicago, but who, the firm says, is swindling doctors by obtaining money without giving any return. The man is reported as a Swede or German-American, with a broken accent, about five feet, six inches tall, heavily built, clean shaven, with a very full face, a pasty white complexion, a rather protruding lower lip and dark moist hair; he is well dressed, has a suave manner, displays several valuable diamond rings and wears a large blue stone in his shirt front. He has given the name of Amos Cato, but he has given many other names. The William Meyer Company state that he does not represent them and that warrants are out for his arrest at Tacoma and Seattle. His method of swindling is to solicit orders and to obtain money as payment or partial payment for the goods, without making a return for the money.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Aug. 19, 1909.

Reform in Pharmaceutical Studies

The superior council of public instruction has during its last session been considering the reform of the course of studies leading to the pharmacists' diploma. According to the new plan, which will go into force Nov. 1, 1910, the pharmaceutical course will last five years; one year of apprenticeship or *stage* in a laboratory (to be required without exception), and four years of academic work. The apprentice or *stagiaire* must be 16 years old and have graduated from the secondary schools. On completion of the *stage* the candidates will pass an examination; during the four academic years, candidates will take sixteen quarterly terms of school work and will pass six examinations.

The Selection of Physicians by Pauper Patients

The law of July 15, 1893, in regard to medical charity, permits each community to choose the method of dispensing this charity; thus there are two systems in use. In fifty-nine departments the pauper selects his own physician, while in others, especially in Paris and in the Department of the Seine, the administration selects a physician. In Paris these physicians, numbering 240, are chosen for three years by the prefect of the Seine and their appointments are renewed from one three-year term to another. They receive a salary in proportion to the number of paupers in the districts which they have to visit, without regard to the number of visits. This system is to-day in disfavor. The municipal council inclines toward permitting the patient to select his physician and the Chamber of Deputies is considering an amendment of the law to this effect. The law on industrial accidents recognizes the principle that to deny the patient the right to select his physician is to interfere with personal liberty, and various medical associations are demanding that the same liberty should be accorded to paupers as to the victims of industrial accidents. Under the new system physicians would be paid according to the legally established scale for industrial accidents, which is lower than the ordinary scale of fees, and it is said that the expenses would be no higher than under the present system.

A New University

As soon as it meets the Senate will consider a bill passed by the Chamber of Deputies to reorganize the Schools of Higher Education of Algiers into a university, and to change the School of the Practice of Medicine and Pharmacy of Algiers to a mixed college of medicine and pharmacy.

An Educational Campaign Against Quackery

A medical periodical, the *Médecin de campagne* has inaugurated a contest open to French-speaking physicians, the object being the composition of an antiquackery circular, intended for the public at large, to be written in a clear and striking style on the dangers of quackery, the methods and the sources of the fortunes of quacks, their exploitation of the credulous, and the difference between men of real scientific achievement and commercial promoters. Thousands of copies of this circular will be given out by the *Médecin de campagne* to medical societies and to physicians for circulation among their patients.

French Association of Urology

The thirteenth session of the French Association of Urology will be held Oct. 7-9, 1909, at Paris at the College of Medicine under the presidency of Professor Guyon. The subject for discussion is "Calculi of the Ureter;" the essayist is Dr. Jeanbrau, professor *agrégé* of the college of medicine of Montpellier.

The Tillaux Monument

The monument erected to the memory of Professor Tillaux will be dedicated Oct. 7, 1909, at the amphitheater of anatomy of the hospitals.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Aug. 11, 1909.

Personals

Death is claiming our distinguished gynecologists at a fearful rate. While Pfannenstiel and Runge have left us within the last few weeks, Prof. v. Rosthorn at Vienna has just succumbed to an apoplectic stroke while hunting. [A notice of this death appeared in The Journal, August 21, page 647.] The deceased was closely related to us in Germany, as he was for some years director of the gynecologic clinic of Heidelberg. From thence he was called two years ago to Vienna.

The filling of the position of director of the medical clinic at Greifswald has taken a singular course. In a quite unusual way Professor Stern, at Breslau, who received a call last April (after repeated refusal of other professors), has twice accepted and again declined the position. I am unaware of the reasons for this conduct. The first assistant of Professor Kraus has now been appointed in his place, and it is to be hoped that the Greifswald clinic has at last a director.

The director of the medical policlinic in Strassburg, Professor Kohts, has resigned his position, and the assistant of Professor Müller in Munich, Dr. E. Meyer, has been appointed chief of the policlinic. A rearrangement of the university faculty has also occurred at Freiburg. In place of Professor de la Camp, who, as I reported sometime ago, is the successor of Bäumler as director of the medical clinic, Privatdocent Dr. Morawitz of Heidelberg has been appointed. In addition, a new extraordinary professorship for children's diseases has been established, and Professor Salge of Göttingen, a pupil of Heubner, has been selected for the chair.

Duke Karl Theodor of Bavaria, the well-known ophthalmologist, celebrated his seventieth birthday, August 9. This princely colleague is the author of a number of very creditable scientific articles in the field of ophthalmology. For many years he has had an extensive practice, and his skill, particularly in cataract operations, is celebrated. However, as he treats the patients gratis he infringes considerably on the practice of the neighboring ophthalmologists, and these have often complained regarding this matter. Nevertheless, the duke enjoys a remarkable degree of respect among physicians in Bavaria with regard to professional relations since, so far as consistent with his position, he has supported the efforts of physicians for the improvement of their economic condition and social standing. Munich and the well-known health resort, Tegernsee, where the duke resides most of the time, have given him the freedom of the city on the occasion of his birthday.

The Campaign Against Quackery

The medical profession in western Bavaria, the Rheinpfalz, have adopted a new method of combating the patronage of quacks by the public; they have passed a resolution to refuse medical aid to such families as first call in a physician in case of injury and then, with reckless disregard of the same, allow quacks to assume the after-treatment. A single visit in case of necessity is to be excepted. It can not be denied that such a resolution will restrain many from carelessly exchanging the physician for a quack, but this measure will secure as little real success as others, and, moreover, may be the occasion of hardships to many.

Spread of Typhoid

This year as usual a relatively larger number of typhoid cases occurred in the German empire in the months of July and August. To what this explosive increase of typhoid morbidity at this time of the year is to be referred has not been surely determined. It is partly due to the greater movement of the population which takes vacation journeys in these months, and partly to the harvest work which is distributed over large areas of land. In almost all these cases the occurrence of the typhoid epidemic is due to water infection. Such has been shown to be the cause of a marked epidemic which prevailed in Altwasser, a large village of upper Silesia, which is inhabited chiefly by miners and factory workers. In this relatively small district in the course of a few weeks 622 cases of typhoid occurred, fortunately with the light mortality of 32 (5.1 per cent.). Moreover, the military maneuvers which take place in these months give occasion for the origin and increase of typhoid. Thus in Hanover 21 cases of typhoid fever were found in one army corps, and those attacked had taken part in an exercise of the ambulance corps, during which the infection must have occurred, according to the investigations made. In this epidemic there were no deaths. The mortality of typhoid is less than formerly. Great stress is laid on rendering typhoid bacillus carriers harmless, as their importance for the spread of typhoid is becoming more and more recognized. The government of Saxony published an edict in June according to which district physicians must direct their attention to individuals who permanently excrete typhoid bacilli, report them to the authorities and inform the persons concerned regarding the danger for their environment which they constitute. Bacillus carriers who deal with food supplies must abandon such an occupation.

The Isolation of Advanced Consumptives

While extensive provision is made for consumptives in the initial stages the care of those in advanced stages leaves much to be desired. They are not received into the sanatoria, as a cure is out of the question, and the funds must not be sacrificed for useless therapeutic efforts. On the other hand, it is generally recognized that there is a constant danger of the spread of tuberculosis especially by these patients. B. Fränkel, and especially Robert Koch, have for many years emphasized the fact that the important factor in fighting tuberculosis consists less in curing consumptives than in the making incurable consumptives harmless. All measures which have been used heretofore to secure the isolation of such patients have had little success. The construction of special invalid homes or separate departments for such patients in the hospitals with rest-rooms and gardens has been tried. But such institutions have naturally the character of houses to die in, and are therefore feared and avoided by the patients. For this reason the isolation of these patients in institutions in which both curable and incurable patients may find a place in separate departments is favored. Moreover, the attempt to place consumptives in small cottage homes in the neighborhood of their previous home must be regarded as hitherto a failure. The number who can be isolated in this way is relatively so small that it has no influence on the suppression of tuberculosis. Under the circumstances it is necessary at present to leave these patients in their homes and to secure their isolation as far as possible by means of instructions and nursing. An improvement could be secured if the introduction of compulsory notification of tuberculosis should provide a legal ground for the removal of patients from their homes and their isolation in hospitals. To be sure, the prospects for such a measure, which is already in existence in other countries, is very small in consideration of the present composition of our legislative bodies.

Division of the Ministry of Education

A reorganization of the Prussian ministry of education (*Kultusministerium*), the necessity for which I have formerly noted, will, as I can authoritatively state, be accomplished in a short time. The department, which consists of three divisions, will give up the medical bureau, which will be attached to the department of the interior, so that the *Kultusministerium* will hereafter include only matters of education and the affairs of the church. Whether this transfer of medical affairs to the department of the interior will be of advantage for the public health and for physicians I very much doubt. On the whole, the business will be conducted in the same way as heretofore. A positive advance can be secured only by another organization, that is to say, by the unification of all sanitary matters which are now distributed through a series of departments (thus, railroad hygiene is cared for by the department of railroads, hygiene of trades and buildings by the department of public works), and by granting a greater independence to the medical division. The establishment of a special medical department would be of the greatest importance, but there is no prospect of carrying out such a project, aside from other difficulties, in consequence of the present unsatisfactory financial condition of Prussia in spite of the financial reform.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Aug. 15, 1909.

Death of Eminent Viennese Professors

Within a short time, two gynecologists of our university senate died unexpectedly, and their loss is deeply felt by the profession. The younger, and the better known of the two, Prof. Alfons von Rosthorn, was only 52 years old. He was in his younger days assistant to Breisky and Chrobak, both well-known obstetric and gynecologic surgeons, whose professorship in the Vienna Allgemeines Krankenhaus meant an epoch of brilliant scientific achievements. Rosthorn soon was offered a professorship in Graz, later on in Heidelberg, and when two years ago Chrobak retired from his post in Vienna, the brilliancy of Rosthorn's researches and his fame as a surgeon prompted the Vienna medical faculty to elect him as Chrobak's successor. Under his supervision, in cooperation with Schauta, the new clinics were finished and many valuable suggestions were offered by the newly appointed professor. When in 1908 he finally took over the charge of the new clinic, he laid special stress on the teaching of the students, imbuing them with the motto: "Primum non nocere." He soon drew many students to his lectures, for he had the gift of filling their minds with the enthusiasm of the investigator. The short space of time in which he had the opportunity to make himself prominent in Vienna only showed how much we have lost by his death. Rosthorn's chief attention was directed to the diseases of the adnexa of the female genitourinary system, and his main merit during his short activity here lay in the fact that he insisted on a prolonged term of service for each student as an interne at the hospital. The other man whose death came as a shock to his numerous friends and pupils was G. C. Lott, professor of obstetrics and gynecology, and director of the gynecologic department of the Poliklinik. Lott was a conservative but energetic surgeon, whose anatomic researches form the foundation on which the teaching of the pathology of the lower uterine segment is based. He reached the age of 66 years.

Pellagra in Austria: New Report

Since 1905 the action of the government in suppressing pellagra has been going on and including all affected areas. Altogether a population of 2,250,000 has been investigated with the result that about 78,163 persons (3 per cent.) were found to be suffering from one form or another of the disease. Certain districts were more affected than others, and as a rule, the poorer classes succumbed more easily than those who could procure the food regarded as necessary. The measures of the government have been of a prophylactic nature. Apart from instituting bakeries with an ample supply of good flour, where the people could obtain good bread at a minimum price, salt and quinin were distributed freely, it having been observed that the exhibition of these substances had a marked effect on the course of the disease. The action of the government (described in THE JOURNAL, Aug. 1, 1908, li, 420) has since last year cost about $45,000, and the benefit derived by it has prompted several corporations in the affected eastern provinces of the empire to assist the board of health in its efforts by generous gifts. Thus the funds at disposal will enable the extension of the action to all afflicted districts. Out of the cases treated within the last two years, there were recurrences in 126.

Regulations Concerning General Anesthesia

Some regrettable accidents, among them a death from the effects of narcosis before operation, have prompted the government to revise the regulations dealing with general anesthesia for hospitals. The following points have been especially worked out: In a hospital anesthesia must not be produced except by a special anesthetist. In no case may a surgeon anesthetize and operate at the same time, except in an emergency, when necessary to save life. If in a hospital a nurse or student is entrusted with the administration of the narcotic substance, such individual must be controlled and assisted by a qualified surgeon. The surgeon should select the kind of narcosis as well as satisfy himself of the purity of the chemicals used, as the entire responsibility rests with him. Whenever possible, the open method should be preferred, and the A. C. E. mixture is recommended, unless pure ether is required. Special stress is laid on the necessity of examination for the presence of the much-feared "status lymphaticus." Every month reports of the number of anesthesias, the duration and the result, along with the kind and quantities of narcotic substance used, have to be sent to the board of health. Needless to say, in each case of fatal narcosis a very strict postmortem examination has to be made to find out the reason for the death.

Correspondence

The Turner Memorial Fund

To the Editor:—The late Dr. J. Edward Turner, the founder and projector of the first inebriate asylum in the world, built at Binghamton, N. Y., died in indigent circumstances and was buried at Wilton, Conn. No stone or monument marks his burial-place.

Dr. Turner was the first man to point out the practical possibilities from the medical study and treatment of inebriates in an institution, and to indicate that the great alcoholic problem must be solved by a scientific study of the inebriate and the nature and influence of alcohol. His views were severely ridiculed; and he was persecuted as a crank, but this only increased his ardor, energy and self-sacrifice. He was a century ahead of his day and generation, and his writings and books indicate a knowledge of the subject which even now is just beginning to dawn on the minds of the most advanced students.

Now that the alcoholic problem is coming into prominence, and is so intimately associated with the great hygienic problems of the day, it should be the privilege as well as the duty of American physicians to recognize Dr. Turner's marvelous work and studies in some manner.

A committee (of which I am chairman) has been appointed by the Society for the Study of Alcohol and Other Narcotics to solicit subscriptions for the purpose of erecting over Dr. Turner's grave a monument costing about $600 or $700. Dr. L. D. Mason, 171 Joralemon street, Brooklyn, the treasurer of the Turner Memorial Fund, will receive and acknowledge contributions of any amount for this purpose. Subscribers to the fund will receive a copy of Dr. Turner's "History of the First Inebriate Asylum in the World," a volume of 500 pages, published a short time before his death, and containing an account of the struggles and beginnings of the first institution at Binghamton. It is proposed to hold, when the contributions are sufficient, a formal dedicatory service at Wilton, Conn., at which addresses will be delivered in memory of Dr. Turner and his work.

Correspondence is solicited either with Dr. Mason or with the undersigned. T. D. CROTHERS, M.D., Hartford, Conn.

The Pneumococcus-Carrier a Possible Danger

To the Editor:—"An Epidemic of Empyema," reported in THE JOURNAL, Aug. 14, 1909, p. 529, leads me to ask if one case developed in advance of the others, and if the author, or some other person had, within a few hours following a visit to the home of the first pneumonia patient, come in contact with the persons who afterward developed pleuritis?

It is interesting to know how extremely susceptible some persons are to pulmonary infection, especially the old and the young and those having a tendency to such troubles.

I conducted a series of experiments on the possibility of the conveyance of infection in the laboratory of the late Professor Miller of Berlin in which the saliva of a visiting physician was found to contain the elements of the diseases of the various cases, seen by him, more than an hour after leaving them. Among these were pneumonia cases. I found that after the mouth and nares were sterilized the saliva would not produce pneumonia, septicemia, etc., as it did before sterilization.

I am inclined to believe that pneumonia as well as measles, scarlet fever, diphtheria, etc., might be carried from house to house, causing epidemics, unless the physician and visitors are sterilized after leaving the sick chamber.

It seems to me that this is a subject worthy of consideration by the U. S. Public Health and Marine-Hospital Service.

G. LENOX CURTIS, New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

POISONING FROM MRS. POTTER'S WALNUT JUICE HAIR STAIN

To the Editor:—In THE JOURNAL of August 14, I noticed a report of a dermatitis following the use of Mrs. Potter's Walnut Juice Hair Stain. I wish to report another due to the same preparation.

History.—On July 6, 1909, I was called in to see a middle-aged woman who, for a week, had had a dermatitis of scalp, back of neck and ears, shoulders and scapular region. She complained of intense itching and soreness.

Examination.—The skin over the scalp, back of neck and ears and shoulders was very red and swollen; scattered here and there were papules, vesicles, pustules and scabs. The scalp especially was very pustular. Itching and pain were severe especially in scalp. The patient said the eruption had broken out immediately following a second application of Mrs. Potter's Walnut Juice Hair Stain, first application having been just two days preceding second application.

Treatment.—I advised washing the hair and scalp with green soap and water daily and using a soothing antiseptic ointment. The dermatitis cleared up in four days.

WILLIAM W. WOOD, M.D., Jamestown, N. D.

To the Editor:—My excuse for reporting the following case of dermatitis venenata caused by the use of Mrs. Potter's Walnut Juice Hair Stain is based on two grounds: Marked edema and induration of tissues involved and the intractable course of the disease.

., a woman aged 59, called me May 20, 1909,
uption on head and neck of several days'
hair dye was at once surmised owing to the
color of the hair with gray roots under-
limited having used Mrs. Potter's Walnut
vo occasions, two days apart, the eruption
ours after the last application.

Examination.—The face and neck were covered with a papular eruption, the inflamed borders of which had coalesced presenting a uniform deep, dusky red color extending from the hair line to the clavicles. The lower eyelids were very edematous and the left ear was indurated and swollen to twice the normal size. The right ear was of a dusky red color, but without papules or swelling. Heart and kidneys were apparently normal, temperature and pulse remaining normal throughout the course of the disease.

Treatment.—The itching and burning were relieved for a short time only by cooling lotions, the prescriptions having to be changed at frequent intervals, to give continuous relief. The usual antipruritic ointment gave no relief at all, the patient declaring that "salves" made the itching worse. While the symptoms were reasonably relieved by treatment, the dermatitis with the edema of eyes and thickening of ear persisted for six weeks. In the third week a scattered papular eruption appeared on the chest and shoulders. In this location the itching was not so intense. At the end of six weeks the eruption had faded and the edema had almost disappeared. the sensation of burning remaining—without itching—for some time after the skin had cleared up.

E. A. HANNUM, M.D., Cleveland, O.

To the Editor:—I have just seen a patient poisoned as described by Dr. Schalek (THE JOURNAL, Feb. 13, 1909) by the Potter hair dye. This woman had used several other so-called walnut juice stains, but was not poisoned until she applied the Potter product.

EDWARD NORTON EWEN, M.D., Oakland, Cal.

COMMENT.—Other cases of poisoning due to this preparation have been reported in THE JOURNAL as follows: One case Feb. 13, 1909; one case March 6, 1909; two cases April 3, 1909, and one case Aug. 14, 1909. The subject is referred to editorially in this issue.

PROPOSED SECTION ON PSYCHIC FORCES

To the Editor:—The suggestion by Gustavus Werber in THE JOURNAL, August 28, p. 731, to establish a section on psychic forces in the American Medical Association merits the encouragement of the members of the profession.

Around the accredited and orderly facts of our science of medicine there floats a sort of dust cloud of exceptional phenomena at times and places that can not readily be ignored but which always is more easy to ridicule than to explain. No part of this mystical phenomena has been treated with a more contemptuous scientific disregard than the mass of phenomena generally termed psychic. Lord Kelvin, then Sir William Thomson, in the president's address of the British Association for the advancement of science in 1871, laid down a dictum that should be the motto for all true scientists the world over. He then said: "Science is under bonds, by the eternal principles of honor, to look fearlessly in the face of every problem that is presented to her." The physician is now interested in psychotherapeutics and this subject no doubt can not gain much progress until a lot of other phenomena along that line shall also receive the attention that they rightly merit.

In Europe many of the leading scientists and physicians are interested in these phenomena. I heartily agree that we in America can not afford to lag behind in this movement and believe that the medical man is the right man to study it, for he of all others is best prepared and has the best opportunity.

DANIEL S. HAGER, M.D., Chicago.

The Public Service

Medical Department of the Army

Changes for the week ended Aug. 28, 1909:

Rhoads, Thomas L., major, August 20, left Walter Reed Army General Hospital on 10 days' leave.

Hughes, Leonard S., 1st lieut., M. R. C., August 15, left Department Rifle Range, Cal., en route to Fort Lawton, Washington, for duty.

Wells, F. M., 1st lieut., M. R. C., August 18, left Fort Robinson, Nebr., en route to Fort Leavenworth, Kan., for duty with troops to Des Moines, Iowa.

Tukey, Willim H., 1st lieut., M. R. C., granted 21 days' leave of absence about Aug. 20, 1909.

Harris, Jesse R., capt., ordered to proceed from Fort George Wright, Wash., to Boise Barracks, Idaho, for temporary duty.

Baily, Howard H., capt., granted 15 days' leave of absence when his services can be spared.

McLellan, George H., 1st lieut., M. R. C., ordered to proceed from Fort Crook, Nebr., to Fort Des Moines, Iowa, for duty with troops of the 2d Cavalry to Des Moines Iowa.

Brown, O. G., capt., ordered to proceed from Fort Robinson,
Nebr., to mil at Des Moines, Iowa, for duty
with Second from Fort Leavenworth, Kan.
Allen, John ve of absence for two months.
Snyder, He on expiration of present leave
of absence to proceed to New York City on business connected with the Medical Supply Depot, and on completion of same to proceed to St. Louis, and assume charge of the Medical Supply Depot in that city, relieving 1st lieut. Ferdinand Schmitter, M. C., who will return to Jefferson Barracks, Mo.

Barney, Fred M., 1st lieut., M. R. C., granted 15 days' leave of absence about Sept. 10, 1909.

Clark, Joseph T., major, Brown, Orville G., capt., Van Dusen, James W., capt., McLellan, George H., Bastion, Joseph E., Miller, Albert L., Wells, Francis M., Burket, John A., 1st lieuts., M. R. C., ordered to proceed to Des Moines, Iowa, to arrive not later than September 17, to participate in a military tournament at that city, September 20 to 25, and on termination thereof, to return to their proper stations.

Sweazey, Verge E., capt., granted two months' leave of absence on surgeon's certificate of disability.

Cutliffe, Wm. O., 1st lieut., M. R. C., granted leave of absence for one month on surgeon's certificate of disability.

Craig, Emmett J., dental surgeon, granted leave of absence for two months.

Mills, Robert H., dental surgeon, ordered to Fort Riley, Kan., for temporary duty.

Sanford, Joseph L., 1st lieut., M. R. C., granted 30 days' leave of absence to take effect on or about Sept. 2, 1909.

Jackson, Thomas W., 1st lieut., M. R. C., on being relieved from temporary duty at Washington Barracks, D. C., by Major C. R. Reynolds, will proceed to Fort Washington, Md., for temporary duty, and on return of Captain Samuel J. Morris, will proceed to Fort Hunt, Va., for duty.

Hart, James W., 1st lieut., M. R. C., relieved from additional duty at Fort Washington, Md., and duty at Fort Hunt, Va., and ordered to proceed to Cayay, P. R., for duty.

Hutton, Paul C., capt., granted leave of absence for one month.

Davidson, Wilson T., capt., relieved from duty in the Philippine Islands, and assigned to duty as surgeon of the transport *Buford,* on the voyage commencing Sept. 16, 1909, and on arrival at San Francisco will report to The Adjutant General of the Army for further orders.

Fox, James S., 1st lieut., M. R. C., ordered to Fort Andrews, Mass., for temporary duty, and on its completion, to return to his proper station.

Stallman, George P., 1st lieut., M. R. C., granted leave of absence for one month, with permission to apply for 15 days extension.

Medical Corps of the Navy

Changes for the week ended Aug. 28, 1909:

Peck, A. E., surgeon, detached from the Marine Recruiting Station, New York, and ordered to the Marine Recruiting Station, San Francisco.

Murphy, J. A., surgeon, detached from the *Olympia*, August 27, and ordered to the Marine Recruiting Station, New York.

Rennie, W. H., P. A. surgeon, detached from the *Rhode Island*, and ordered to the Marine Recruiting Station, New York.

Grieve, C. C., P. A. surgeon, detached from duty at the Naval Hospital, Sitka, Alaska, and ordered to the *Independence*.

Brister, J. M., P. A. surgeon, detached from the *Independence* and ordered home to wait orders.

Sinclair, J. A. B., asst.-surgeon, ordered to command the Naval Hospital, Sitka, Alaska.

Brooks, F. H., asst.-surgeon, ordered to the Naval Recruiting Station, Omaha.

Sterne, C. F., asst.-surgeon, detached from the Naval Recruiting Station, St. Louis, and ordered to duty at the Naval Hospital, Puget Sound, Wash.

Thomas, G. C., asst surgeon, detached from the Naval Recruiting Station, Omaha, and ordered to the *Rhode Island*.

Steadman, W. G., asst.-surgeon, discharged from treatment from the Naval Hospital, Norfolk, Va., and granted sick leave for six weeks.

Reed, T. W., asst.-surgeon, detached from the Marine Recruiting Station, San Francisco, and ordered to examination for promotion and then to wait orders.

Bloedom, W. A., acting asst.-surgeon, ordered to duty at the Naval Medical School Hospital, Washington, D. C.

Fauntleroy, A. M., P. A. surgeon, detached from the *Hartford*, August 29, and granted leave for one month.

Johnson, J. T., acting asst.-surgeon, ordered to duty at the Naval Hospital, Naval Hom

Reeves, I. S. K., P. from treatment at the Naval Medical School D. C., and granted sick leave for one month.

Reeves, I. S. K., P. A. surgeon, unexpired sick leave revoked, ordered to the Navy Yard, Philadelphia, September 3.

Kuder, W. S., asst.-surgeon, detached from the Navy Yard, Philadelphia, September 3, and ordered to Washington, D. C., for examination for promotion and then to wait orders.

Sutton, D. G., asst.-surgeon, detached from the Naval Academy and from the *Tonopah* and ordered to duty in connection with the *Vestal* and to duty on board that vessel when commissioned.

Public Health and Marine-Hospital Service

List of changes for the seven days ended Aug. 25, 1909:

Kalloch, P. C., surgeon, granted 7 days' leave of absence en route to station.

Wasdin, Eugene, surgeon, granted 1 month's leave of absence from Aug. 22, 1909, on account of sickness.

Geddins, H. D., surgeon, detailed to represent the Service at the 6th International Medical Congress to be held at Budapest, Hungary, Aug. 29-Sept. 4, 1909.

Rosenau, M. J., surgeon, directed to proceed to Philadelphia, on special temporary duty.

Corput, G. M., P. A. surgeon, granted 10 days' leave of absence from Aug. 13, 1909, on account of sickness.

Vogel, C. W., P. A. surgeon, granted 3 days' leave of absence from Aug. 23, 1909, under paragraph 189, Service Regulations.

Gwyn, M. K., P. A. surgeon, granted 7 days' leave of absence from Aug. 17, 1909, under paragraph 191, Service Regulations.

Stimson, A. M., P. A. surgeon, granted 7 days' leave of absence from Aug. 16, 1909, under paragraph 191, Service Regulations.

Ebersole, R. E., P. A. surgeon, on expiration of present leave of absence, relieved from duty at Manila, P. I., and directed to proceed to San Francisco.

Wollenberg, R. A. C., asst.-surgeon, granted 2 months' leave of absence from Sept. 10, 1909.

Altree, G. H., acting asst.-surgeon, granted 30 days, leave of absence from Sept. 2, 1909.

Boyd, Frank, acting asst.-surgeon, granted 22 days' leave of absence from Aug. 20, 1909.

Fogarty, J. N., acting asst.-surgeon, granted 18 days' leave of absence from Sept. 4, 1909, with pay, and 12 days' leave of absence from Sept. 22, 1909, without pay.

Frissell, C. M., acting asst.-surgeon, granted 20 days' leave of absence from Aug. 13, 1909; 9 days with pay and 11 days without pay.

MacCaffry, Ward B., acting asst.-surgeon, transferred from Reedy Island Quarantine Station to Cape Charles Quarantine Station, effective Sept. 1, 1909.

O'Rielly, W. J., acting asst.-surgeon, granted 2 days' leave of absence from Aug. 31, 1909.

Thornton, M. J., acting asst.-surgeon, granted 1 day's leave, Aug. 15, 1909, on account of sickness.

Health Reports

The following cases of and deaths from smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service during the week ended Aug. 27, 1909:

SMALLPOX—UNITED STATES

California: Berkeley, July 24-31, 1 case; San Francisco, July 26-July 3, 1 case.
District of Columbia: Washington, Aug. 7-14, 1 case, 1 death.
Indiana: Fort Wayne, Aug. 7-14, 13 cases; South Bend, 1 case.
Iowa: Cedar Rapids, July 1-31, 1 case.
Kansas: Wichita, July 31-Aug. 7, 2 cases.
Missouri: St. Louis, Aug. 7-14, 2 cases.
Montana: Butte, Aug. 5-12, 7 cases.

SMALLPOX—FOREIGN

Belgium: Antwerp, July 17-24, 4 cases.
Canada: Halifax, July 31-Aug. 7, 1 case.
China: Amoy, June 26-July 3, 8 deaths; Kang Thau, June 1-30, 1 case, April 1-June 30, 7 cases, 1 death; Shanghai, July 3-10, 1 death, among natives.
Egypt: Cairo, July 1-8, 1 case, 1 death.
France: Paris, July 24-31, 1 case.
Italy: General, July 25-Aug. 1, 14 cases; Naples, 22 cases, 2 deaths.
India: Bombay, July 6-13, 7 deaths; Calcutta, June 26-July 3, 5 deaths; Madras, July 3-9, 1 case, 1 death; Rangoon, June 26-July 3, 3 deaths.
Mexico: Guadalajara, July 22-29, 1 death; Monterey, Aug. 1-8, 1 death; Veracruz, vicinity, Aug. 12, 6 cases.
Peru: Lima, July 17-24, 1 case.
Russia: Moscow, July 10-24, 71 cases, 9 deaths; Odessa, July 17-24, 4 cases; St. Petersburg, July 10-17, 18 cases, 3 deaths.
Spain: Barcelona, July 19-Aug. 2, 4 deaths; Tarragona, July 19-26, 1 death; Valencia, July 10-17, 6 cases; Vigo, July 24-31, 1 death.
Tripoli: Tripoli, July 10-24, 17 cases, 6 deaths.
Turkey: Constantinople, July 25-Aug. 1, 1 death.

YELLOW FEVER

Brazil: Para, July 10-31, 8 cases, 8 deaths.
Ecuador: Guayaquil, July 10-24, 6 deaths.
Mexico: Colima, Aug. 19, present; Medida, Aug. 6-13, 1 case.

CHOLERA—INSULAR

Philippine Islands: Provinces, June 26-July 3, 110 cases, 92 deaths.

CHOLERA—FOREIGN

China: Amoy, June 26-July 3, 11 deaths; Hankau, July 10-17, 1 case, 1 death; Kang Thau, June 1-30, 2 cases, 1 death, April 1-June 30, 4 cases, 2 deaths.
India: Bombay, July 6-13, 17 deaths; Calcutta, June 26-July 3, 56 deaths; Madras, July 3-9, 1 death; Rangoon, June 26-July 3, 2 deaths.

PLAGUE—INSULAR

Hawaii, Hilo, vicinity, Aug. 19-20, 1 cases, 1 death; Olas, Aug. 20-22, 2 cases, 2 deaths.

PLAGUE

Azores: Terceira, June 16, 3 cases.
Chile: Antofagasta, July 10, in Lazaretto; Iquique, July 11, 7 cases, July 16, 7 cases.
China: Amoy, June 26-July 3, 95 deaths, July 10-17, 73 deaths; Kang Thau, June 1-30, 37 cases, 19 deaths, April 1-June 30, 117 cases, 59 deaths; Hongkong, July 3-10, 4 cases, 2 deaths.
Ecuador: Guayaquil, July 10-24, 4 deaths.
India: General, July 3-10, 558 cases, 462 deaths; Bombay, July 6-13, 21 deaths; Calcutta, June 26-July 3, 41 deaths; Rangoon, 22 deaths.
Japan: Shikoku, July 28, 5 cases, 1 death.
Peru: General, July 3-10, 10 cases, 8 deaths.
Venezuela: Garacas, Aug. 6, 1 case.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arizona: Phœnix, October 4-5. Sec., Dr. Ancil Martin.
Colorado: Capitol, Denver, October 5. Sec., Dr. S. D. VanMeter, 1723 Tremont St.
Georgia: Regular, Capitol Bldg., Atlanta, October 12. Sec., Dr. E. R. Anthony, Griffin. Homeopathic: Atlanta, October 4. Sec., Dr. R. E. Hinman, 153 Whitehall St.
Idaho: Boise, October 5-6. Sec., Dr. W. F. Howard, Pocatello.
Illinois: Coliseum Annex, Chicago, October 20-22. Sec., Dr. J. A. Egan, Springfield.
Kansas: Topeka, October 12. Sec., Dr. F. P. Hatfield, Olathe.
Louisiana: New Orleans, October 1-2. Sec., Dr. Felix A. Larue, 211 Camp St.
Michigan: Lansing, October 12-14. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.
Minnesota: State University, October 5. Sec., Dr. W. S. Fullerton, 214 American National Bank Bldg., St. Paul.
Mississippi: Jackson, October 12. Sec., Dr. S. H. McLean.
Montana: Capitol, Helena, October 5. Sec., Dr. W. C. Riddell.
New Jersey: State House, Trenton, October 19-20. Sec., Dr. E. L. B. Godfrey, Camden.
North Dakota: Grand Forks, Oct. 5-7. Sec., Dr. H. M. Wheeler.
Oklahoma: Ione Hotel, Guthrie, October 13. Sec., Dr. Frank P. Davis, Enid.
Rhode Island: Room 313, State House, Providence, October 7-8. Sec., Dr. Gardner T. Swarts.
Utah: Room 207, City and County Bldg., Salt Lake City, October 4-5. Sec., Dr. G. F. Harding, 310 Templeton Bldg.
Wyoming: Laramie, October 20-22. Sec., Dr. S. B. Miller.

Additional Data for the Educational Number

In the list of medical colleges given on page 555 of The Journal, Aug. 14, 1909, the Educational Number, the University Medical College of Kansas City should have been included. That college has adopted the requirement of one year of collegiate work for admission in addition to a four-year high school education, the requirement to go into effect with the session of 1910-11.

Dr. Seneca Egbert, dean of the Medico-Chirurgical College of Philadelphia, writes that instead of 56 graduates, as published on pages 538 and 548 of the Educational Number, that college had 78 graduates.

At a meeting of the faculty of the Starling-Ohio Medical College of Columbus, held since the reports were sent to us, Dr. W. J. Means was elected dean, vice, Dr. George M. Waters.

A new medical building which will be completed about January 1, 1910, is now being erected by the Eclectic Medical Institute at Cincinnati. It will be a six-story structure, will cost about $50,000, and will be connected by covered bridge with the Seton Hospital. Special provision is made for laboratories, lecture rooms, offices and a library.

Medical Economics

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

The outline for the first weekly meeting of the postgraduate course for the third year is given herewith. Owing to unavoidable delay in preparation of the copy, the pamphlets containing the outline for the third year have not been printed, but are in course of preparation and will be ready for distribution by the middle of the month. County secretaries and others desiring copies of the third year course are requested to write Dr. Blackburn, stating the number of copies desired, etc., as the entire edition will be sent to Dr. Blackburn for distribution.

Third Year—First Month, First Weekly Meeting

SURGICAL DISEASES OF THE THORAX

ANATOMY OF THORACIC WALL AND DIAPHRAGM

THORAX: Shape, size, diameters, variations in sexes; osseous boundaries, sternum, ribs, vertebrae. Sternum, shape, location, costal and muscular attachments. Ribs, number, general characteristics and peculiarities. Dorsal vertebræ, characteristics and peculiarities. Costo-sternal and costo-spinal articulations. Muscles, vessels, nerves.

STERNAL REGION: Pectorals, triangularis sterni; internal mammary and branches, veins and lymphatics; nerves.

COSTAL REGION: Pectorals, serratus magnus, external and internal intercostals, number, attachments, functions; intercostal arteries, origin, relations, axillary branches; veins; lymphatics; nerves.

DIAPHRAGM: Position, shape, attachments, portions, openings.

ANATOMY OF LUNGS AND PLEURA

PLEURA: Parietal layer consisting of costal, mediastinal and phrenic portions, important relations of each; visceral layer, reflections, relations; pleural sinus. Mediastinum, portions, important contents of each, lymphatic glands.

LUNGS: Shape, size, costal and mediastinal surfaces, apex, base, borders, relations of structures forming root of lung, bronchial and pulmonary arteries, nerve supply, lymphatics.

ANATOMY OF VASCULAR SYSTEM

PERICARDIUM: Shape, size, layers, relation to chest wall, to surrounding structures, superficial cardiac triangle.

HEART: Size, shape, position, relation to chest wall, to lungs and pleura, muscular structure, situation of valves.

AORTA: Three portions, boundaries and relations of each.

SURFACE ANATOMY

REGIONS OF CHEST: Anterior, posterior, lateral. Outline of heart; apex beat; valves. Outline of lungs; of pleura.

Marriages

H. BROOKER MILLS, M.D., to Miss Caroline Wagner, both of Philadelphia, June 18.

WILLIAM E. PETERS, M.D., Carlisle, Pa., to Miss Mary L. Cain, of Philadelphia, August 20.

RALPH H. AUGUR, M.D., Washington, D. C., to Mrs. Stella H. Townsend, at Washington, August 16.

J. CLINTON MOBLEY, M.D., to Mrs. Julia Catherine Hanson, both of Memphis, Tenn., at Marion, Ark., August 8.

RALPH C. TILLEY, M.D., Lawrenceburg, Ind., to Mrs. Mattie C. Bell Chance Calvert Harris, of Chesterville, Ind., recently.

Deaths

Hiram Landis Getz., M.D. Jefferson Medical College, Philadelphia, 1874; for many years a member of the American Medical Association; first vice-president of the Iowa State Medical Society in 1897; president of the International Association of Railway Surgeons in 1901; president of the Iowa State Railway Surgeons Association in 1899; and first vice-president of the Tri-State Medical Society in 1900; formerly professor of obstetrics and diseases of women and children in the Iowa College of Physicians and Surgeons, Des Moines; for several years city physician of Marshalltown, Iowa, and first physician of Marshall county; chief surgeon of the Iowa Central Railway; district surgeon of the Chicago and Northwestern Railway and local surgeon of the Chicago Great Western Railway; formerly captain and assistant surgeon in the Iowa National Guard and later lieutenant colonel and a member of the governor's staff; president of the local board of U. S. pension examining surgeons; president of the board of education of Marshalltown, and postmaster of that city in 1894; was found unconscious in his room in Jacksonville, Fla., from the effects of morphin and died in St. Luke's Hospital, August 19, aged 57.

Lewis Balch, M.D. College of Physicians and Surgeons, New York City, 1870; formerly professor of anatomy and medical jurisprudence in Albany Medical College; consulting surgeon to St. Peter's Hospital, and attending surgeon to the Child's Hospital; health officer of Albany, and secretary to the State Board of Health; a member of the American Public Health Association; formerly surgeon of the 37th, 71st and 10th regiments, National Guard, State of New York; surgeon of the Second New York Infantry, U. S. V., during the Spanish-American war, and afterward a surgeon of volunteers in the Philippine Islands; in 1900 superintendent of sanitary improvements at Colon, Panama; died in his rooms at the Army and Navy Club, New York City, August 9, aged 62.

Edwin Lesley Marechal, M.D. University of Alabama, Mobile, 1870; a member and president of the Medical Association of the State of Alabama; formerly lecturer on hygiene and medical jurisprudence in his alma mater; one of the organizers of the Baldwin County Medical Association, and county health officer for several years; in 1890 organizer and president of the Alumni Association of the University of Alabama, Medical Department; health officer of Mobile county, and president of the Medical Society of Mobile in 1895; a member of the State Board of Censors, and first editor of the *Mobile Medical Journal*; for fifteen years a member, and for seven years president of the school board of Mobile county; died at his home in Mobile, August 19, aged 59.

Robert Wesley Erwin, M.D. Bellevue Hospital Medical College, New York City, 1870; of Bay City, Mich.; a member of the American Medical Association, American Academy of Medicine and Bay City (Mich.) Board of Health; a member of the local board of U. S. pension examining surgeons; a veteran of the Civil War; at one time superintendent of schools of Harrison county, Ohio, and professor of geometry in the Cooper Institute, New York City; died suddenly at Grand Lake, Mich., August 13, from heart disease, aged 67.

George Francis Shears, M.D. Hahnemann Medical College, Chicago, 1880; president and senior professor of surgery in Hahnemann Medical College; and one of the most prominent homeopathic practitioners of the middle west; consulting surgeon to the Cook County, Streeter and Silver Cross hospitals, attending surgeon to Hahnemann Hospital, director of the Chicago Tuberculosis Institute, and assistant editor of the *Clinique*; died at his home in Chicago, August 27, from paresis, aged 52.

Joseph Alison Scott, M.D. University of Pennsylvania, 1889; of Philadelphia; a member of the American Medical Association; fellow of the College of Physicians of Philadelphia, and a member of the Philadelphia Pathological and Pediatric societies; adjunct professor of clinical medicine in his alma mater; visiting physician to the Pennsylvania Hospital; died at the summer home of his sister in Northeast Harbor, Maine, August 13, from heart disease, aged 44.

Casper K. LaHuis, M.D. University of Michigan, Ann Arbor, 1896; of Zeeland, Mich.; formerly of Kalamazoo and a member of the school board; a member of the Michigan State Medical Society and Kalamazoo Academy of Medicine; formerly assistant in obstetrics and gynecology at his alma mater; died at his home, August 12, from tuberculosis, aged 40.

John Wherrell, M.D. Kansas City (Mo.) Medical College, 1889; professor of internal medicine in the Western Eclectic College of Medicine and Surgery, Kansas City, Kan.; founder of the Kansas Normal School, Paola; and for many years superintendent of schools of that city and Leavenworth; died at his home in Kansas City, Kan., August 12, aged 66.

George Washington Moran, M.D. University of Michigan, Ann Arbor, 1892; a member of the American Medical Association; treasurer of the Michigan State Medical Society; surgeon to the American Shipbuilding Company; chief of staff of St. Vincent's Orphan Asylum, Detroit; died in Harper Hospital, Detroit, August 12, from ptomain poisoning, aged 41.

Adelbert G. Gumaer, M.D. University of Pennsylvania, Philadelphia, 1883; of Buffalo, N. Y.; a member of the American Medical Association; for twenty-three years local surgeon to the Lake Shore and Michigan Southern Railway, and surgeon to the Emergency Hospital; died in Santa Monica, Cal., August 1, from heart disease, aged 57.

Peter James Campbell, M.D. New York University, New York City, 1893; a member of the American Medical Association and the Utica (N. Y.) Medical Library Association; formerly health officer of Utica; died at his home in that city, August 10, from acute nephritis, aged 41.

Gioachino Barabini, M.D. University of Palermo, Sicily, 1901; a member of the American Medical Association and the Italian Medical Society; prominent as a worker among the Italian poor of New York City; died at his home in New York City, August 16, from gastroenteritis, aged 34.

Edward Mortimer Hardcastle, M.D. University of Maryland, 1889; formerly principal of the Easton (Md.) High School and Maryland Nautical Academy; a clergyman of the Protestant Episcopal church; died in Easton, Md., August 15, from tuberculosis, aged 41.

Charles Edward Trotter, M.D. Johns Hopkins University Medical School, 1909; acting assistant surgeon U. S. Navy; was drowned August 11, from a life raft, after the sinking of the U. S. Naval tug, *Nezinscot*, off Cape Ann, Mass., aged 25.

George H. Bailey, M.D. Tulane University, New Orleans, 1861; a surgeon in the Confederate service during the Civil War; formerly of Phoenix, Ariz.; died at the home of his daughter in Anaheim, Cal., August 4, from bronchitis, aged 70.

Joseph H. Hobson, M.D. Washington University, St. Louis, 1895; a member of the American Medical Association; formerly a member of the city council and school board of White Cloud, Kan.; died at his home in that city, July 29, from tuberculosis, aged 40.

John T. Martin, M.D. Cincinnati College of Medicine and Surgery, 1871; formerly of Green Camp and Marion, Ohio; a veteran of the Civil War; died in the Old Soldier's Home, Sandusky, Ohio, August 16, from paralysis, aged 65.

John D. Shaw, M.D. Willamette University, Salem, Ore., 1895; of Salem, Ore.; for several years physician to the Oregon State Penitentiary; died in the Salem Hospital, August 6, from cerebral hemorrhage, aged 47.

Joseph Edward Smith, M.D. Georgetown University, Washington, D. C., 1900; a member of the Kentucky State Medical Association; died at his home in Bardstown, August 14, from Hodgkin's disease, aged 32.

Samuel P. Oldham, M.D. Kentucky School of Medicine, Louisville, 1875; died suddenly at his home in New Castle, Ky., August 12, from cerebral hemorrhage, aged 53.

Charles I. Conover, M.D. Albany (N. Y.) Medical College, 1878; died at his home in Charleston Four Corners, N. Y., August 8, from intestinal obstruction, aged 57.

Levi Fulk, M.D. Bellevue Hospital Medical College, 1874; died at his home in New Kingston, Pa., August 8.

Charles Oxford, M.D. University of Berlin, Germany, 1873; died at his home in Omaha, August 6, from pneumonia.

Medicolegal

General Unsoundness of Mind as a Defense to Crime

The Supreme Court of Pennsylvania says, in the homicide case of Commonwealth vs. Hallowell, where the whole defense rested on general unsoundness of mind, that whether this condition can be urged as a sufficient defense against an accusation of crime depends on the extent and degree of the unsoundness. Any variation, however slight, from normal conditions, implies unsoundness in some degree; and ordinarily, when one is said to be unsound mentally, the expression indicates nothing as to the extent or degree of the variation. There is, however, nothing uncertain or indeterminate in these words when they are used to denote the mental unsoundness which exempts from legal responsibility for what otherwise would be felonious and therefore criminal homicide. The words used in this connection have a fixed and definite meaning. They denote a mind so far devoid of understanding that it is unable to distinguish between right and wrong, and is therefore without freedom of moral action. However unsound in mind a man may be generally, it is only when he has lost utterly his power of moral perception that he ceases to be responsible in the eye of the law. Therefore it is that, whenever insanity is set up as a defense to an accusation of crime, it becomes the duty of the trial judge to clearly define to the jury what kind or degree of insanity absolves, to the end that they may intelligently understand the real point at issue and weigh with discriminating judgment the evidence submitted to them.

The trial judge told the jury in this case that the question was not, "was this prisoner of unsound mind? or, if you choose to put it so, was he insane?" Again, he said: "The question is not whether he is eccentric or peculiar, or what these people (witnesses) call unsound." In his instruction the judge was strictly within the law. What the jury were to determine was a question of legal accountability; and, since this could exist even where there was unsoundness, the statement of the judge was not only entirely correct, but, in view of the character of the testimony he was about to review, it was none too direct or positive; for, however correct the defendant's witnesses were in the opinions expressed that the defendant was a man of unsound mind, it was manifest from the facts given by each in support of such inference, with a few exceptions, that the unsoundness they were considering was not that which in law exculpates.

Evidence of general unsoundness is admissible, of course, for it is only when the whole mental condition of the accused is exhibited that the extent or degree of the insanity can be determined.

Admissible Evidence of Injury to Spine

The Court of Appeals of Kentucky says, in Lexington Railway Co. vs. Woodward, a personal injury case brought by the latter party, that a physician who had made an examination of the plaintiff's person qualified himself to testify as an expert, and the examination which he testified he made was sufficient to enable him to give an opinion on the extent of her injuries. He could testify to any physical fact which he found to exist. He was properly allowed to state that the left leg below the knee was smaller than the right, and that this indicated in his judgment a lack of nutrition. It was true that the plaintiff sued for an injury to her spine and hip; but any symptom on the lower part of the leg which would be confirmatory of the testimony as to the condition of the spine and hip was properly admitted. In spinal injury, effects are often shown in other parts of the body, and if there were no such evidence in other parts it would be a circumstance indicating that the plaintiff's spine was not so badly affected as she claimed.

Procedure in Montana After Revocation of License

The Supreme Court of Montana says, in State, on the relation of Gattan vs. District Court, that the relator was, prior to Nov. 23, 1907, a physician duly licensed by the State Board of Medical Examiners. Complaint having been made to the board that he had been guilty of unprofessional and dishonorable conduct, a trial was had and the board revoked his license. He appealed to the District Court, which held trial Nov. 23, 1907, with a jury of six physicians in conformity with the statute, Section 1588 of the Revised Codes of Montana. The trial resulted in a verdict finding the charges sustained and affirming the judgment of the board of examiners, and judgment was by the court entered accordingly.

The relator subsequently filed in the Supreme Court his application for a writ of review to annul the judgment so entered against him. It was alleged that the District Court was without jurisdiction to render and enter the judgment because the jury selected to try the charges was not a legal jury, in that the names of the persons constituting it were not drawn from the regular jury box in conformity with the provisions of law on the subject, but that the jurors were selected under arbitrary order and direction of the court, and that the jury, as constituted, consisted of six persons only, whereas the relator was entitled to have the issue involved tried by a constitutional jury of 12 persons, drawn and impaneled as provided by law for all actions and proceedings in the district. But the application must be denied for two reasons:

1. The relator had a right of appeal from the judgment. While proceedings had under the law before the board of medical examiners touching the granting or revoking of a license may not in any sense be regarded as the administration of a judicial remedy an appeal to the District Court from one of its determinations, whereon a trial of the issue is had de novo (anew), must be regarded as an application to that court for a judicial remedy. The appeal is granted as a method of getting the matter involved before a court that it may be determined judicially. It is a special proceeding commenced in the District Court by the filing of the appeal. In all such proceedings the party aggrieved has an appeal to the Supreme Court, provided he avails himself of his right within one year. He may not permit the time for appeal to lapse and then have the judgment reviewed on writ of review.

2. The application did not question the jurisdiction of the District Court to entertain the appeal from the board to it. The only question made with reference to the proceedings there was as to the action of the court in selecting the jury. Its action in this regard, if erroneous, amounted only to error within jurisdiction, and could not be corrected by writ of review. The application for a writ of review must therefore be dismissed.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

Medical Record, New York

August 21

1 *Life-Insurance in its Relation to Prevention of Tuberculosis. S. A. Knopf, New York.
2 *Report of Nine Cases of Pellagra. E. D. Bondurant, Mobile, Ala.
3 *Value of Microscopic Examination of the Prostatovesicular Secretion in the Diagnosis and Prognosis of Gonococcus Infection. A. L. Wolbarst, New York.
4 *Multiple Sclerosis. C. D. Fox, Philadelphia.
5 Malformations of the Nasal Septum. J. P. Lewis, Waltham, Mass.
6 Flat Feet. M. Strunsky, New York.
7 *Conservatism in the Use of Flatfoot Plates. R. O. Meisenbach, Buffalo.

1. **Life Insurance and Tuberculosis.**—Knopf believes that in the future the insurance companies will be able and glad to aid in the distribution of literature and information on tuberculosis, and especially its prevention among the public with whom they deal; that the life-insurance agent may by word of mouth impart this instruction, that the people who undertake industrial insurance are alive to the necessity of prevention of tuberculosis, and that they will gladly insure their children against tuberculosis. The Metropolitan Life Insurance Company desires to erect a sanatorium for its employés, which may later be used by policy holders.

2. **Pellagra.**—Bondurant observed a considerable number of cases among negroes in the insane asylum at Mt. Vernon, Ala. In his private practice he saw none before August, 1907, but from that time until May 1, 1909, he saw 9 out of 590 cases seen in all. He reports 9 cases in detail, most of them having been fatal.

3. **Microscopic Examination of Prostatovesicular Secretion.**—Only those cases in which 3 or more examinations were made of the prostatovesicular secretion are included by Wolbarst in his paper. He selected 35 cases because these cases emphasize certain features of this subject that are of more than passing interest. From 3 to 19 examinations of massaged secretion were made in each of these cases, a total of 240 examinations. These patients have been divided into two classes: (1) Those who showed clinical symptoms and came to be treated for them—21 in number; and (2) those who did not show clinical symptoms, but came for examination for some other complaint, or for advice preparatory to marriage—14 in number.

As a result of these investigations, Wolbarst believes that a man may be "cured" of his gonorrhea, so far as symptoms are concerned, and his prostate and adnexa may contain gonococci; that gonococci may be found in clear urine; that gonococci may persist in the prostate for many years, and show no symptoms of any kind; they may not be infectious necessarily; that we can not tell whether or not any given prostate contains gonococci, except by making a large number of examinations of the massaged secretion after stimulation and irritation by silver nitrate, etc.; that though it is conceded that cultures are more certain, when successful, than microscopic examinations, practicing physicians must rely on the microscope for their results. Besides, a negative finding in a culture tube is no more enlightening as to the absence of gonococci in the prostate than is a negative finding on a microscopic slide. In either case the thing sought for has merely not been found, which is a different thing from saying that it is not there. The gonococcus should be sought for until every means is exhausted.

4. **Multiple Sclerosis.**—Fox reports a case in which at first examination the absence of nystagmus, intentional tremor, and impairment of speech caused the incorrect diagnosis of transverse myelitis. Hysteria made its appearance late. The diagnosis was based on transitory but almost total paralysis, the induction of hypnoidal states by lateral fixation of the eyes, and the appearance of an apparently causeless series of syncopal attacks. There were no other stigmata of hysteria except contraction of the visual fields.

7. **Flatfoot Plates.**—Meisenbach emphasizes the harm that may be done by the promiscuous use of flatfoot plates when applied by persons without skill and knowledge.

8. **Intravenous Administration of Strophanthin.**—Stone agrees with Liebermeister that the intravenous injection of strophanthin enables one to carry along a certain number of severe cases of pneumonia until the patient is able to eliminate the toxin of the pneumococcus and to get on the sure road to recovery. He says that in certain cases of collapse, due to cardiac weakness, the physician has in strophanthin a drug which will act promptly and powerfully and enable the patient to rally, and the heart to resume its work. The large amounts of urine which have been passed by these patients make it seem that the strophanthin has also to do with the production of what Meltzer has called the "life-giving diuresis," by means of which the toxic products are more rapidly eliminated than would otherwise be the case. When a patient has grown weaker and weaker in the course of his disease, whether it be pneumonia or typhoid fever, the cardiac stimulant action of strophanthin will apparently have little effect on the gradually flagging heart action.

In a case of attempted suicide by means of carbolic-acid poisoning, combined with gas poisoning, the patient had a very rapid, almost tic-tac, heart, which was regular, but the sounds were very faint, the pulse of small volume and poor tension. The stomach was washed out; strophanthin was given in a half-milligram dose, and the pulse soon became markedly stronger, and the next morning was very good. There was suppression of urine, but after twelve hours 15 ounces of urine were drawn, and after this the amount of urine excreted rose to 40 ounces in the next twenty-four hours. In a sudden postoperative collapse, an almost imperceptible pulse of about 150, became fairly strong, and 120 in rate within five minutes after the administration of a milligram of strophanthin. From that time on the pulse grew stronger and the patient was no longer a source of anxiety.

11. **Tubal Abscess.**—Chute believes his case to be of interest not only because of the unusual position of the tubal abscess, but also from the fact that both kidneys, without giving evidence of any infection, were excreting great numbers of organisms. The patient, a woman aged 28, had been delivered of her first child toward the latter part of September. The labor was a long one, and the child was stillborn. According to the history, delivery was followed by a serious postpartum hemorrhage, and later by an attack of sepsis, lasting ten or twelve days. After delivery, it was noticed that there was a visible mass to the left and below the umbilicus. This was supposed to be a much-enlarged uterus. The woman was treated locally for subinvolution, but without effect on the mass. It occupied the place where this patient, when about seven months pregnant, had had an attack of very acute pain, lasting some hours and requiring morphin. The upper limit of this mass was just below the level of the umbilicus. Though there was moderate distention, the mass was perfectly evident on simple inspection. There was tympany over it. It was immovable and moderately tender. Vaginal examination showed a uterus that was unusually high, but not much enlarged or fixed. No connection could be made out between the uterus and the mass. Nothing could be felt in either broad ligament.

An incision over the most prominent part of the tumor showed a mass covered with thickened omentum that lay just to the inside of the descending colon and was adherent to it. The uterus was pulled up and tilted to the left by the left tube, which disappeared into the mass about three-fourths of an inch from its junction with the uterus. A portion of the left ovary projected from the mass above. The left broad ligament was stretched out in such a way as to cover the true pelvis on the left. The ureter could be easily seen coursing through the lower part of the ligament. In attempting to separate this mass from the colon, an abscess cavity was opened and some drams of offensive pus escaped. The cavity was drained by a tube and wicks. No attempt was made at its removal. After the operation, drainage from the cavity was profuse. Gas was passed by rectum and feces as a result of enemas. The distention, however, increased and there was marked peristalsis. On the second day there was pain in the right iliac region, with rigidity at this point. On the third day a fecal fistula appeared, evidently from a perforation of the colon at the point where the attempt was made to separate it from the mass. Though the fistula discharged profusely, it did not affect the distention to any considerable degree. On moving the gauze that had been used to wall off the pelvis, there was a gush of amber-colored fluid from the right side of the pelvis. This fluid was clear and not offensive. No cultures were taken of it. The patient died on the fourth day after operation, apparently as a result of the localized peritonitis in the right pelvis and the chronic sepsis from which she had been suffering. No autopsy was obtained.

13. **Sarcoma.**—The patient, a woman, 73 years of age, had a small lump in the right side of the neck 51 years ago. There is no pathologic report of the specimen removed. There was no return of the trouble until nine years ago, when a bunch began to grow at the site of the old scar. At the time of its removal the tumor was the size of an orange. There is no pathologic report of this specimen obtainable. Two years later, seven years ago, another bunch appeared in the same place and was removed. No pathologic report can be found. December, 1906, she was admitted to the hospital for a growth in the right side of the neck, extending from the median line in front to the median line in the back. Nearly the entire surface of the growth was sloughing, with an intensely fetid odor. The tumor was removed in one mass with a wide skin margin by Smith. The external jugular vein and the facial artery were ligatured and divided; the submaxillary gland and all palpable lymphatic glands were dissected out. It was impossible to close the wound, which, however, healed promptly by granulation without skin grafts. The tumor weighed one pound and was a round-cell sarcoma. In June, 1908, the patient was again admitted to the hospital, presenting in the old scar a tumor the size of an egg. The tumor mass and several glands were removed and the wound sutured. The incision healed by first intention and the patient was discharged in ten days.

The second patient, a woman 72 years of age, accidentally struck her knee against a projecting stick in a wood pile. Two weeks later she noticed a hard lump on the injured knee at the site of the abrasion, which had healed promptly. In six weeks it was the size of an egg, bluish-black in color, and proved to be a small round cell sarcoma.

14-15. **Leprosy.**—The papers by Penrose and Ashmead are an excellent exposition of present knowledge of leprosy, especially with reference to the disease as it appears in the United States and in the Bahama Islands.

16. **The Pharyngoscope.**—Hays describes an instrument which, he says, will be an aid to the expert in difficult cases in which either the patient's oropharynx is sensitive or narrow, or in which it is impossible to see clearly the various parts that one wishes to examine. The latest model of the pharyngoscope is composed of a horizontal and a vertical shaft which join each other at right angles, at the outer third, so that the instrument may be used as a tongue depressor. The inner portion of the horizontal shaft consists of a central circular tube with an electric light carrier on either side, the three components being incorporated in a flat piece of metal. From the inner end project the two electric lights which are water tight, give an intense illumination and become only warm enough to keep vapor off the lens. In the central tube is inserted the telescope, which is made on the principle of the Otis cystoscope. To the eye-piece is attached a little metal ball which indicates the position of the lens. This horizontal shaft, including the telescope, is about eight inches long. The widest portion of the instrument, which is at the extreme inner end, is less than five-eighths of an inch, and the flat metal shaft itself measures less than one-half an inch in diameter. The vertical portion is about six inches long and half an inch wide. It is attached to the horizontal portion by a screw joint, and contains the wires for connection with the rheostat or dry cells. Near its upper portion is an arrangement for cutting off the electric current so that the lamps need not be turned on until the instrument is in the mouth.

On account of the cement which holds the lens in place, the instrument can not be boiled, but like the cystoscope it is best disinfected by formalin. For that purpose a metal box is supplied with the instrument which is large enough to contain the horizontal shaft (except the eye-piece), which has a receptacle at one end for formalin tablets and cotton. The instrument is inserted into the mouth like a tongue depressor until the inner end of the telescope is about one-sixteenth of an inch from the pharyngeal wall. When once in place it is held firmly by the examiner, the patient is told to close his mouth and to breathe quietly through the nose. As soon as the mouth is closed, it is observed that the muscles are relaxed and that the nasopharyngeal space is much enlarged. An excellent view of the parts to be seen can be obtained by gazing through the eye-piece of the instrument. In order to keep the patient from breathing in the examiner's face a small mica plate is supplied which is placed between the telescope and the horizontal shaft.

17. Abstracted in THE JOURNAL, May 15, 1909, p. 1611.

19. **Geriatrics.**—Nascher suggests this term as an addition to our vocabulary to cover the same field in old age that is covered by the term pediatrics in childhood.

20. **Glandular Extract and Tetany.**—Ott and Scott made 133 observations on 60 cats and 2 dogs. The cats were first etherized; then the parathyroids were removed under antiseptic precautions. The thymus was always examined for parathyroids. The cat has usually four parathyroids, but more may exist. In young cats, the parathyroids have a looser anatomic relation to the thyroid than later in life. In the cats the parathyroids are about the size of a date seed and have the color of a miliary tubercle. In many cases some of the thyroid was removed in the desire to obtain all the parathyroids, but enough thyroid was left to maintain its functions. When removal in part of the parathyroids was ineffectual to produce a tetany, then the thyroid was also removed and they always found it contained a parathyroid larger than the normal. In cats when all the parathyroids were removed symptoms of tetany came on in about forty-eight hours, as a rule. The first symptoms were a slowness in movement and a state of apathy. The animals were disposed to remain in one place. First, as a rule, there developed a lifting of the posterior extremities and sometimes of the anterior, as though the animal had been stepping in water. The posterior extremities were stifflike in movement and spread apart in their gait. Then trembling ensued in the extremities, followed by convulsions of the whole body. In the convulsive state the animal usually made loud cries before and after the convulsion. Conjunctivitis was frequently noted in the tetania parathyreopriva. The sense of hearing, sight, smell and taste remained. They did not respond to petting. They also had the projecting abdomen noted by Hagenbach.

28. **Epidemic Pneumonia.**—In family P., of 10 exposed, 7 contracted the disease. In family C., of 8 exposed, 4 contracted the disease. In family R., of 6 exposed, 2 contracted the disease. In family R., of 5 exposed, 2 contracted the disease. Besides these 14 cases, 3 cases occurred independently; there was no case of reinfection that Mann knew of. All except 2 of the patients were under 12 years of age, and the physical signs in some of these cases for a time were frequently indefinite. There was considerable gastric and abdominal disturbance. Mann followed the usual expectant plan of treatment with the result that all his patients recovered.

69. **Mechanism of Occlusion of Tube.**—Ries points out that the infectious contents of an inflamed tube escape through the abdominal end, and we find, therefore, here the oldest changes in the peritoneum, such as chronic thickening of the serosa. This makes a peritonitic ring around the ostium out of a

peritoneal ring. The ring need not be a complete one; part of the ring may be formed by any organ that the contraction of the peritonitic scars brings together. These peritonitic scars, like all peritonitic scars on hollow organs, have a tendency to contract. The escape of fluid from the tube is thereby impeded; the swollen folds of the tube have not sufficient room; the tube becomes dilated; the wall of the tube becomes stretched. The fibrous cicatricial ring gives less than any other part; therefore, the muscular coat and its serosa becomes stretched more than the ring around the ostium. With the inflammation subsiding, as tubal inflammations so frequently do, the contents are absorbed or discharged in one direction or another, the swelling of the folds subsides, the walls become too large and loose. The peritonitic ring thereby gains in mobility and can contract further over the fimbriæ.

The fimbriæ escape being pinched by the ring, or, rather, the fimbriæ being covered with epithelium can not adhere to the peritonitic ring, and escape inward without inversion. The ring can now close completely, and we have a closed tube. The union of the peritonitic ring is a seroserous one, and is therefore—when recent—not very firm, so that by squeezing it, we can force it open and see the fimbriæ inside. At this the septic contents of the tube extend into the channel between the mucous surfaces of the fimbriæ. The remnant of peritoneum on the inside of the funnel and on the serous surfaces of the fimbriæ being in a condition of peritonitis, the peritoneal surfaces can fuse with each other in many conceivably irregular ways, while the mucous surfaces of the tubal fimbriæ being covered with epithelium, do not fuse. The remnant of the cleft between the mucous surfaces of the fimbriæ is then sometimes seen as a small dimple on the inside, which leads to an obturating membrane—the original peritonitic ring.

The fimbriæ are now bunched on the inside of the tube, not really inverted. But if the fluid contents of the tube are again absorbed or discharged into the uterus and the tube collapses, the fimbriæ can not open again on account of the peritonitic adhesions outside, but the bundles of fimbriæ can become more prominent on the inside now, because the distention has stopped, and then such specimens as Orth mentions can be obtained. A new dilatation of the tube will then tend to flatten out all folds of the mucosa, and if the seroserous union between the fimbriæ is strong enough the unyielding lines of fusion will stand out like the radii of a rosette.

70. **Constipation in Women.**—The treatment of chronic constipation as outlined by Kohn is dietetic, mechanical and medicinal. There are, he says, a certain number of cases which can be improved by diet alone. Food rich in cellulose and other waste matter is useful in a large proportion of cases. Best of all is a pure vegetable diet, combined with cooked fruits and coarse cereals. To these may be added certain chemical stimulants, such as common table salt, fats, best taken in the form of butter or olive oil (if the latter is well borne), sugar of milk and malt marrow. If still unsuccessful, one may make a trial of the various bulky mechanical stimuli to the intestine, such as bran, vaselin, if it can be taken, and even sand. If all these dietetic schemes fail, the physician may resort to mechanical means before trying medicines; Kohn has found them valuable adjuvants to the diet in a number of cases. Of these, the best are rectal electricity, given three or four times a week with the abdominal pad localized over the affected area. Any kind of rectal electrode may be used and the treatment given for ten minutes. Faradization with an interrupter is the most effective in bringing up the tone of the bowel in atonic cases, whereas in spastic conditions galvanization carefully applied, with the anode in the rectum, is often beneficial. Other means, such as massage of the diseased portion of the bowel, cold sprays, either of ether or ethyl chlorid, may be of assistance. In stubborn cases oil injections or cool salt water, the last especially when the sphincter is weak, may be added. If, however, as often occurs, the patient drifts back to the old state as soon as the treatment is stopped, or often in spite of all treatment, one must call into requisition the various cathartics.

75. **Induction of Labor at Term.**—During the last three years Wright has induced labor within three days after the patient has reached term as a matter of routine in all cases. The following report will illustrate to some extent the methods employed and the results obtained: Mrs. B., aged 30; second pregnancy, expected confinement, June 10. On the evening of June 10, the nurse was summoned, and on her arrival prepared the patient for labor. On the following morning a vaginal tampon was introduced, after which the patient got up and went about the house as usual, suffering no inconvenience from the tampon. Next morning, June 12, the tampon was removed and another introduced. When this was removed on the following day, June 13, the cervix was softened, os softened and slightly dilated, pelvic floor and vulva softened and dilatable. A bougie was then introduced into the uterus and a tampon into the vagina. Uterine contractions commenced about midnight, fourteen hours after introduction, and the child was born four hours after. Labor was easy.

It was noticed in this and other similar cases that it was easy to induce labor at term. The patient is not, as a rule, excited or alarmed. *After the tamponade the patient* can generally go about and do her ordinary work, and sometimes does not even know that the vagina is plugged. As a rule, she does not know after the introduction of the bougie that anything of the sort is in the uterus. After such introduction, however, it is not considered advisable to allow the patient to walk about. The vaginal tampon appears to have a two-fold effect: First, it softens and dilates the cervix and tends to cause uterine contractions. Second, it softens and dilates the vagina, pelvic floor, and perineal body in a way that makes expulsion or extraction through these parts much more easy than under ordinary circumstances.

78. **New Hydrostatic Dilator.**—Reynold claims that his hydrostatic dilator has for its chief advantage the ease with which it can be introduced into the parturient cervix canal without resorting to an anesthetic. It consists of a reinforced rubber bag with a hollow rubber stem perforated with four holes and a solid rubber tip which extends to within one-half inch of the base of the bag. In its collapsed condition it resembles a right-angle triangle, the stem being a part of the perpendicular. To introduce the bag, a blunt-pointed metal stylet is inserted into the rubber stem until it impinges against the solid rubber tip; the bag is then rolled around the rubber stem as one would roll an umbrella. The rolled bag, which is about the size of one's middle finger, is held in the palmar surface of the hand, with the tip of the bag even with the tips of the index and middle fingers. The labia are separated, and the bag, anointed with glycerin, is inserted into the vagina until the finger-tips touch the posterior lip of the cervix. Force is exerted on the stylet by the external hand and the bag is gently pushed through the cervical canal. The fingers of the internal hand hold the bag in position while the stylet is being withdrawn. Sterile water is then forced through the rubber stem causing the bag to unroll and become distended. A Davidson or special syringe can be used for the purpose. When the bag is distended it is cone-shaped. A clamp can be placed on the rubber stem and traction made, if indicated.

89. **Hypertrophic Pyloric Stenosis.**—The stenosis in Spalding's case seems to have arisen from an hypertrophy of every muscular integer of the pyloric division of the bowel, and probably dated back to a very early period of the child's intrauterine life.

90. **Galactoxismus.**—Probably the most dangerous poisons occurring in milk are those resulting from bacterial growth. This should lead to renewed efforts looking toward an uncontaminated milk supply. The bacterial growth should be reduced to a minimum and especially is that true of the colon group. Mineral poison may occur in the milk from the use of metal containers, but this is not a common source of poisoning. Of the medicines excreted by way of the milk, senna and calomel should be especially borne in mind. Probably no other drugs, when given to the mother in ordinary medicinal doses, would appear in the milk in sufficient quantities to poison an infant. Fruit acids and alcohol are not thus excreted. In California, aside from the plants which affect the taste, odor and color of the milk, but are not otherwise of moment, probably the death camas is the only one that needs to be watched for and this only in the northern valleys. This question, however, should be more carefully studied, and it is quite possible that more plants will be found to poison the milk. Dairy cattle should be fed on well-cured alfalfa or wheat hay, and not be allowed to wander at random in a pasture. Even harmless weeds often change the odor and taste of the milk, and, doubtless, to some extent, tend to upset the infant's digestion.

102. **Duodenal Ulcer.**—Einhorn says that the treatment should at first be medical. In the mild cases regulation of the diet (frequent meals, abstention from highly seasoned substances, acids and too fatty foods), improving the general condition by means of iron, arsenic, cold sponging, good air, avoidance of bodily exercise, and the use of alkalies, are sufficient to effect a considerable amelioration, if not a cure. In several cases, olive oil (two tablespoonfuls morning and evening) seemed to be of service. In graver cases of duodenal ulcer (hemorrhages, severe pain, etc.) a strict ulcer cure, with rest in bed and rectal elimination, and afterward fluid diet, must be instituted. In these cases large doses of magnesia and bismuth are of benefit; calcined magnesia, 0.5 gm. (8 grains) bismuth subnitrate, 2 gm. (30 grains), in powders —one powder three times a day, one-half hour before meals. If a strict rest cure has been unsuccessful, or if we have to deal with severe hemorrhages endangering life, and returning frequently, or if obstinate spasm of the pylorus occurs, associated with severe pains in the pyloric region and slight peristaltic restlessness of the stomach, an operation (usually gastroenterostomy) is indicated.

In duodenal ulcer the clinician must advise surgical treatment sooner than in gastric ulcer, as the former, through its complications (hemorrhages, perforations, stenosis of the pylorus), endangers life much more readily than the latter. Gastroenterostomy in these cases is fortunately attended with good results. The ulcer will then soon heal, as the gastric juice does no longer flow over the ulcerated surface in the duodenum or irritate it. At all events, the dangers of hemorrhage, perforation, and pyloric stenosis are thereby prevented.

103. Abstracted in THE JOURNAL, June 5, 1909, p. 1875.

105. **Typhoid Cutaneous Reaction.**—In a previous paper by Floyd and Barker it was shown that cellular sensitiveness, as shown by the ophthalmic test, lasted only as long as the active stage of the disease. They then sought to determine, if possible, if this sensitiveness affected the skin as well as the conjunctiva, and if so, whether it could be used diagnostically. Typhoid bacilli of high virulence were grown in pure culture on agar-agar for twenty-four hours, at 37 C. The growth was then washed off with normal saline solution and the emulsion incubated for four days. At the end of this period it was sterilized in a hot water bath at 60 C. for one-half hour, and then standardized after the method of Wright. The sterile emulsion was then centrifuged and the clear supernatant fluid used for inoculation. The solution used was considerably stronger than that used in the ophthalmic test, being the extract of one billion bacilli. In some instances centrifugalization was omitted and the whole emulsion used for inoculation, with the result of more marked reactions. A standard solution was used in all instances, and not an emulsion of the homologous bacillus in the individual case. In making the test, exactly the same technic was followed as in obtaining the cutaneous reaction in tuberculosis. In all, there were 48 inoculations on 47 patients, of whom 30 were ill with typhoid fever, 2 with *Bacillus paratyphosus* injection, 2 with unclassified fever (clinically not different from typhoid fever), 8 with tuberculosis, 1 with pneumonia, 1 with acute articular rheumatism, 1 with pernicious anemia, and 2 were apparently normal individuals.

Of the typhoid fever cases, the reaction was positive 19 times, negative 9 times, and rendered unsatisfactory by the patient twice. One of the cases of unclassified fever responded to the test, although giving no other evidence of typhoid infection. Neither of the cases of paratyphoid fever gave any reaction whatever. With the exception of a slight reaction in the patient having pneumonia, all the definite nontyphoid cases gave no reaction. All the positive reactions occurred during the active period of the disease, the single patient who was inoculated twice giving a much more striking result at the first inoculation than at the second. The failure of the cases of *B. paratyphosus* infection to respond to the test may be due to the different character of the organism causing the infection. No attempt has been made to discover how early this reaction appears in the course of the disease. The value of the reaction in diagnosis is problematic.

109. **Deformities of Foot.**—In examining the malformations of the body there is no process more valuable than that of studying the relationship of bony landmarks to one another. In the case of the foot, no such method has ever been advanced, and with this in mind, Feiss selected certain landmarks for study. The ones chosen are the lower posterior corner of the internal malleolus, the tubercle of the scaphoid, and the lower tubercle on the head of the first metatarsal. In order to make proper observations, a standard method of estimation had to be applied. A wooden box was constructed, consisting of three sides—a base, a posterior side, and a lateral side. Its dimensions were 12x12x5 inches. The box was placed on the seat of an ordinary chair. The right foot was

used. The subject stood on the floor with the left foot straight, and the right knee bent. Then the right foot was placed in the box, the calf just touching the edge of the box, and the heel resting in the corner. The weight of the body was therefore transmitted through the left leg. In this way the foot could be examined in a definite and uniform position without weight-bearing.

The points marked were the posterior inferior corner of the internal malleolus, the tubercle of the scaphoid, and the lower tubercle of the first metatarsal. The distance of the scaphoid tubercle from the line connecting the internal malleolus with the lower tubercle of the head of the first metatarsal was measured as follows: A thin transparent celluloid rule provided with a scale was applied to the foot so that its upper edge coincided with the dots on the head of the first metatarsal and on the corner of the internal malleolus. Then the distance of the tubercle of the scaphoid from the edge could be read through the transparent rule by means of the scale (the corners of this rule were cut off so that they would not interfere with the sides of the box. The average age of the 100 young men was found to be 21.6 years, the youngest being 17 and the oldest 34 years. The average distance of the tubercle of the scaphoid from the lines connecting the internal malleolus with the lower tubercle of the head of the first metatarsal was found to be 0.49 inch. In only 9 cases was the tubercle less than one-fourth inch below the line, and in only 4 cases was it more than three-fourths of an inch below the line. Therefore the great majority of cases show the tubercle depressed from one-fourth of an inch to three-fourths of an inch, which in itself is a large variation (one-half inch).

113. **Punishment for Crime.**—Walsh holds that the term insanity is so vague that its use as a plea to enable the criminal to escape punishment is not justifiable in the present state of our knowledge. Responsibility differs in different individuals, but it is never quite eliminated, except in the absolute idiot. For those of lowered mentality, even the animals, punishment has a good effect. Punishment is not revenge, but is meant to deter the individual criminal, and above all to deter others tempted to criminal acts. Punishment is more needed for those of lowered mentality, of whom the expert may well declare that they are insane, than it is for the normal. Subrational individuals with the cunning of the insane will take advantage of our leniency if present conditions are allowed to continue and we shall have a riot of crime by personal violence.

127. **Appendicitis.**—Donohue's patient was taken ill with severe abdominal pain, not localized in any particular spot; temperature was 102 F., and there was some pulse disturbance. This pain continued for two or three days and disappeared. Two weeks afterward the man was taken ill with the same kind of pain in the same locality, attended with fever, lasting a little longer time and finally disappeared. About two weeks subsequently he was taken ill again with pains in the lower abdomen and had some bladder symptoms —frequency and difficulty in urination. He complained of pain in the lower abdomen; difficulty in urinating; no vomiting or constipation, temperature in morning was 102 F.; in evening, 103 F.; pulse was 110 in morning and 120 in evening. On examination a lump about the size of a cocoanut was found in the hypogastric region, extending over to the left side of the umbilicus; it was fluctuating and tender to the touch. A diagnosis of postperitoneal abscess was made and operation advised. An incision was made on the left side, the same that is made for ligation of the external iliac artery, and when the peritoneum was reached to push this aside and open the abscess extraperitoneally. A free incision was made and when the peritoneum was reached it was pushed aside and the lump was carefully examined. It fluctuated and was felt to pass over near the appendical region. By bimanual palpation it was pretty definitely made out that it was of appendiceal origin. The incision was closed, sealed with collodion and dressed. A second incision was made over the appendical site, but a little more internal and the peritoneal cavity opened. The appendix was found in an abscess cavity behind the bladder, perforated at the tip and diseased all the way up to its junction with the cecum. It was removed and the cavity was washed out and drained with a dressed tube. The patient made a smooth recovery.

1. **Progress in Obstetrics.**—That the ideal to be aimed at in obstetric practice is not merely a living mother and a living child, but rather a living healthy mother and a living healthy child, is the keynote of Byers' paper. He cites statistics to show the present condition of obstetric medicine as practiced in two Irish maternities—the Rotunda Hospital in Dublin, the largest midwifery institution in the British Empire, and in the Maternity Hospital, Belfast. From Nov. 1, 1907, to Oct. 31, 1908, 2,060 patients were confined in the Rotunda Hospital with only 7 deaths, and in only 126 was the temperature over 100.4 F.—that is, a percentage morbidity of 6.12. Of the 7 deaths, only 3 were due to infection. One patient was admitted infected, another had been examined outside, and the third was a case of incomplete abortion with a fetid discharge on entering the hospital. In the Maternity Hospital, Belfast, there occurred during 1907 and 1908, 12 deaths out of 1,355 deliveries, and of these only 4 deaths were due to puerperal infection. (In one case the patient had been in labor for twenty-four hours attended by an unqualified midwife before admission; another woman, with a contracted pelvis, had been in labor several days before admission; and in a third case the child was born in an advanced state of decomposition.) Further, in 1908, the cases of morbidity from every cause estimated on the standard that the occurrence of one temperature of 100.4 F. indicated a pathologic condition, were 9.42 per cent., which is distinctly lower than at Hofmeier's well-known clinic. Again, owing to the aseptic and antiseptic management of the mother during her confinement, as well as by the adoption of special prophylaxis in the care of the child, cases of ophthalmia neonatorum in both maternities are now extremely rare. Such splendid results have been brought about by recognizing that, in at least 75 per cent. of the cases, labor is a natural process not needing interference, and that its tendency is to prevent infection, and that our duty is to follow and aid it, and to interfere only when the resources of Nature fail to protect the interests of mother or child. The uncalled for use of the forceps, early rupture of the membranes, douching—unless under very special circumstances—and the improper management of the third stage of labor are things of the past in properly conducted maternities. By the thorough application of the most minute surgical cleanliness as regards patient, nurse, and doctor during labor and the puerperium; by the adoption of Credé's teaching, that internal examination of parturient women should be altogether avoided or restricted within the narrowest possible limits (it can be well replaced by external examination) and by the immediate suture of any laceration occurring during the process of labor, these excellent results are possible of attainment.

2. **Rational Puerperium.**—The mode of management adopted by Haultain is as follows: The puerpera, if willing, is encouraged to sit up in bed to meals on the second day. As early as she feels inclined thereafter she is allowed to leave her bed and sit up for an hour. On the following day this is repeated morning and evening. The next day two hours, morning and evening, are spent out of bed, the patient sitting and walking a little, if she so desires. The fifth day after rising is practically spent out of bed, with the exception of a few hours rest in the afternoon, and on the tenth day the patient leaves the hospital. The number of patients who followed this line of treatment was 100. All the patients sat up in bed on the second day; 40 rose on the third day; 35 rose on the fourth day; 25 rose on the fifth day. Of the 100 cases, 47 were primiparæ and 53 multiparæ. Each was carefully examined before leaving the hospital, and as many as possible six weeks later. The morbidity in these cases—that is, a temperature over 100 F. or pulse over 90 for twelve consecutive hours—was represented by three cases. Two patients developed infective temperature on the third day. One of these left the hospital well on the sixteenth, the other on the twenty-eighth day. Pelvic examination on the day of leaving hospital (tenth to twelfth day) showed the pelvic organs to be normal, except in two cases, where a slight retroversion of the uterus was present. In one case there was considerable varicosity of the veins of the legs, but the woman remarked that it was not nearly so bad as after previous confinements—this being her seventh. All the women examined six weeks and more after confinement showed involution to be thorough, and the position of the uterus normal, with the exception of two, being those previously noted as having retroversion. Many women voluntarily expressed the opinion that they had never felt so well previously, and from the others when asked, there was no dissentient voice.

4. **Head-Nodding in Infants.**—The two cases reported by Gibson had many things in common, confirming the theory advanced by Raudnitz and J. Thomson, who contended that it is due to the dim light in which these babies are living and try to use their eyes, and this theory fits these two subjects well; the seasonal incidence, in the darkest months of the year; the environment—both these babies living during the day in dark, ground-floor rooms, with one window, facing the east, but shut out from most of the sky by tall buildings within a few yards, and neither baby was often in the open air. So far as could be learned the two had never been in contact, but their homes were less than fifty yards apart. The babies recovered under hygienic and dietetic treatment. Both cases ran a course of between five or six weeks.

5. **Clonic Spasm of Diaphragm.**—There would appear to be two ways in which a cervical rib might cause diaphragmatic spasm: (1) by pressure on the vagus in the neck, causing a reflex contraction, much as derangement of the stomach may produce the ordinary hiccough by irritation of the terminations of the vagus in the gastric mucosa; or (2) by so exalting the normal impulse regularly passing down the phrenic nerve to produce the usual inspiratory contraction of the diaphragm by direct irritative pressure on that nerve trunk so as to produce a violent spasmodic contraction of the muscle. The latter appears to Hunt to be far the more probable explanation. In his case the vagus in the carotid sheath lay some distance internal to the cervical rib, whereas the phrenic nerve in its course along the anterior surface of the scalenus anticus muscle must be exposed to pressure of a large cervical rib near the articulation with the scalene tubercle of the first rib. The fact that removal of the rib, alone of the treatments tried, was directly followed by cessation of the spasm, is, he thinks, another argument that the spasm was probably caused by pressure of the rib.

6. **Femoral Hernia.**—Bevers' patient, a woman of 58, had undergone an operation for femoral hernia in the right side three years previously. For six days there had been abdominal pains and vomiting, the symptoms commencing suddenly

while she was at work in her garden; for two days there had been constipation which was not quite complete, as flatus had been passed, and repeated enemata had produced a slight result. When seen, the pulse was 112, temperature normal, the abdomen was distended, and there was some general tenderness. Just below and parallel with Poupart's ligament on the right side there was an old scar, and at the outer extremity of this scar external to the femoral vessel a little thickening could be felt; this small thickening was not tender and the patient declared it had been present ever since the previous operation; there was no swelling in the situation of the femoral canal. Owing to the fatness of the patient, the presence of the old scar and the unusual situation of the slight swelling present, Bevers found it difficult to decide whether the patient was suffering from a hernia strangulated in an abnormal situation, or from some other form of intestinal obstruction. He therefore opened the abdomen in the middle line below the umbilicus; distended small intestine at once presented, and a little examination proved that there was a Richter's hernia into a small hernial opening just external to the femoral artery.

7. **Temporary Removal of Color-Blindness.**—Going on the theory that anything that would improve the movements of the cells ought to have the effect of stimulating the retinal cells to more ready response to color sensations, and as the calcium salts have that stimulating effect on the body cells, Stephens came to the conclusion that a big dose of calcium lactate ought to remove color blindness, if only temporarily. The first patient to undergo the experiment was a medical man whose response to green sensations was *nil*, but who, after only 10 grains of calcium lactate was able to appreciate and differentiate green-colored articles. In the next case, Stephens gave 10 grains of the drug at 2 o'clock, and another 10 grs. at 3. At 4 o'clock he found that response to all the colors was distinctly better. The only objection to the experiment was that the patient had a headache for a few hours afterward. In the third case he gave only 20 grains, but the result was just as satisfactory and quite as conclusive.

19. **Treatment of Morphinism.**—For many years Jennings has been using heart tonics and bicarbonate of soda in morphinism, not as a "cure," but as a part of the treatment which remedies the physiologic disturbances, caused by suppression, and which, by alleviating two of the principal factors of craving, reduces the otherwise intolerable wretchedness of an ordinary weaning to a perfectly bearable minimum. In morphin addicts, morphin and spartein, as well as digitalis are tonics of the heart. Spartein acts in morphin suppression, like morphin, as a perfect and immediate heart tonic, and physiologists and patients affirm that spartein enables these patients to walk up hills or to take active exercise which would otherwise have been impossible. The use of Vichy water is in Jennings' opinion the most valuable symptomatic treatment of the gastric and general hyperacidity of suppression.

The morphin habit is a toxic neurasthenia, a disease of overstimulation, and outside the special indications for cardiac tonics, for a flagging heart deprived of its accustomed stimulation, nearly all of the other somatic symptoms may be looked on as nervo-katabolic. They react on one another as the *ensemble* of the somatic disturbances of function react on psychism. The result of overstimulation is to produce metabolic perversion and to cause fatigue, and the fatigue of the nervous centers in its turn causes katabolic insufficiency, the formation of acids, which keep up a condition of nervous exhaustion by chemical changes of the cells. In ordinary healthy tiredness the acids (phosphoric, lactic, carbonic) are soon eliminated, but when fatigue becomes more or less permanent, as in the toxic asthenia of morphinism, the nuclei of the neurones, which in their normal condition are alkaline, become acid, and this can be shown histologically.

There are many intermediary products of imperfect combustion which can be found in the urine, the more perfect oxidation of which, together with the relief of the discomfort caused by them, can be promoted by bicarbonate of soda. Although Vichy water is not *per se* a "cure" for morphinism, it is a factor in treatment conditioning the efficacy of the *ensemble* of the measures employed. Its administration will make all the difference in the addict's comfort during weaning, and its omission may turn the scale to failure instead of to success. In some exceptional cases, those patients who are determined to give up the use of morphin, if they can obtain sufficient relief, have sometimes found that Vichy water was all that was necessary to diminish the general discomfort to a degree compatible with renunciation.

Liquoris ammonii acetatis	4		ʒj
Aquæ chloroformi, ad	30		℥j

Sig.: Every 4 hours.

No other drugs or stimulants are administered, with the exception of a purgative to open the bowels freely at the commencement of the disease. But a careful watch is kept on the heart, and if this shows signs of collapse, as indicated by a weak and quickened pulse, then cardiac stimulants are called in to aid the failing circulation: the pulse is not relied on alone, because it may be full and not much quickened just before death. When necessary, the following prescription is ordered:

℞.	gm. or c.c.			
Liquoris strychninæ		33	or	m. v
Tincturæ digitalis		46		m. vii
Aquæ chloroformi, ad	30			ʒi

This is given alternately with the iron mixture every six hours, i. e., four doses of each in 24 hours. The number of patients treated with iron alone was six; the remaining four needed the addition of the strychnin mixture; no patient received anything but iron before the fifth day. Besides these medicines, general principles were followed in the management of the cases.

34. **Treatment of Gonorrhea.**—Duer suggests to those in charge of military and large hospitals a trial of Bier's treatment, especially in recent cases in which the inflammation is confined to the anterior part of the urethra. An elastic band about 1 in. broad is applied to the penis 2 inches or so above the meatus, continuously, or intermittently, several hours on and several hours off. Rest in bed during the treatment might or might not be necessary. The tightness of the band would have to be carefully regulated so as, while hindering the venous return, not to stop the arterial supply. Frequent washing away of the discharge by some mild antiseptic would be desirable. In addition, irrigation of the urethra beyond the band might be advisable.

45 *Strangulated Hernia in Infant. (Hernie étranglée chez un nourrisson.) R. de Gaulejac.
46 *Pulmonary Tuberculosis with Cavities in Children. E. Gaujoux and Brunel (continued).

45. **Strangulated Hernia in Infant.**—The strangulation had occurred fifteen days before the child was brought to the clinic; the hernia had been noticed since birth. This long survival could have been possible only with much less toxicity on the part of the intestinal contents than is the case in adults and only with a hernia far along in the digestive tract. An artificial anus would probably have developed spontaneously in the strangulated loop in another day or so. The infant organism has evidently means of adapting itself to functional or mechanical disturbances beyond those possessed by adults. The case encourages, says de Gaulejac, surgical interference even in the most apparently desperate cases in young children.

46. **Pulmonary Tuberculosis with Cavities in Children.**—This article is based on fifty cases, including a number personally observed. Chronic tuberculosis of the lungs is rare in children, but when it does occur the same process of defense is observed as in adults.

57 Abscesses in the Liver and Expectoration of Bile. (Abcès du foie et expectoration biliaire.) A. Valence.

51. **Grafting of Joints.**—Judet describes experimental arthroplasty on dogs, rabbits and cats, the results showing that the joint, as a whole, with its synovial sheath, has a vital autonomy which permits its being grafted into another animal and retaining its vitality. The transplanted cartilage is the only one of the tissues that alters; it requires the action of synovial fluid. In man the transplantation of a joint would be a much simpler procedure on account of the size of the parts. The article is illustrated with the technic worked out on the cadaver. The great difficulty will be to obtain suitable grafting material.

52. **Tuberculosis of the Esophagus.**—Guisez and Abrand have encountered two cases and review one reported by Schrötter giving an illustrated description of the anatomic findings. If the stenosis is of a sclerocicatricial type, dilatation is possible, proceeding very cautiously. In case of ulceration, the indications are the same as for fissure in a sphincter—gentle dilatation to act on the spasm. Local treatment can be by lactic acid or silver nitrate, as for laryngeal tuberculosis, with general measures. The development of esophagoscopy has permitted the differentiation of this form of tuberculosis.

54. **Omentum Shield for Acute Ulceration in the Ileum.**—Solieri was convinced that perforation was imminent in a case of paratyphoid infection. Appendicitis had been diagnosed as the agglutination test for typhoid had been negative. The operation revealed the absence of an acute process in the appendix, but an ulceration was found in the small intestine. He drew up the omentum over the part of the intestine involved and fastened it like a thick muff all around the diseased loop, suturing the omentum to the mesentery in front, above and below and to the intestine on each side of the affected zone. The patient recovered without mishap except for three severe intestinal hemorrhages.

60 *Gastrocutaneous Fistulas Due to Gastric Ulcer. H. M. Jeannel.

58. **Torsion of Uterine Fibromas.**—Torsion was observed by the writers in 23 of 9,000 cases of uterine fibroma. In 55 cases on record in which the puerperal past is mentioned, 12 cases were in virgins and only 36 in women who had borne children. Eight unpublished cases are reported in detail, with fifteen illustrations.

59. **Obliteration of Douglas Pouch in Treatment of Uterine Prolapse.**—The unusually large Douglas pouch in the case reported kept up the prolapse, which was corrected at once by obliterating the cul-de-sac. This was done by running a thread through its walls and drawing it up, repeating this at four points. With forceps a lengthwise fold in the peritoneum was taken up and the needle passed through the fold, and continuing, through six of these folds, to make each one of the four sutures.

60. **External Fistulas Into the Stomach.**—Jeannel presents a second article on this subject, giving the details of 50 cases found in the literature. About 35 operations were performed on 26 of the patients, with a complete cure in 76 per cent. and a fatal outcome in 16 per cent.

76 Posterior Arthrotomy for Irreducible Dislocation of the Shoulder. (Reposition der irreponiblen Schulterluxation mittelst Arthrotomie von hinten.) Madelung.

67. **Transplantation of the Thyroid.**—Salzer implanted the thyroid in the abdominal wall, making a pocket between the fascia and peritoneum or in the muscle, and in this pocket transplanting part of the animal's own thyroid. Of 60 rabbits thus operated on, 23 died, but the results in the remaining 37 show that the organ heals in place and functionates better in thyroidectomized than in normal animals, and that the transplanted gland is able to produce colloid substance and that its vascularization is fully as good as when in its normal place. As only a small portion can be thus transplanted at a time, it is wise to have the technic as simple as possible. It can not be expected that one small piece can supply the total thyroid needs of the organism.

70. **Anesthesia in Germany in 1908.**—Neuber received 112 responses to question blanks sent out to surgeons requesting particulars in regard to their anesthesias during 1908. Chloroform, it seems, was used in 20,613 cases with 1 death to 2,060; ether in 11,859, with 1 death to 5,930; chloroform plus ether in 10,232, with 1 death in 3,410; and the scopolamin-morphin mixed anesthesia in 23,809 cases, with 1 death in 4,762. Local anesthesia or the first whiffs of ether were utilized in fully a quarter of all cases that would have required general anesthesia twenty years ago and no fatality was reported with these methods. In Gurlt's statistics, 1890-1897, there was 1 death in 2,075 chloroform and 1 in 5,112 ether anesthesias, chloroform having been used five times as often as ether, while in Neuber's statistics the scopolamin-morphin mixed technic takes the lead in numbers, and also from the standpoint of prevention of postoperative pneumonia. Kümmell reports only 0.61 postoperative pneumonias in 1908 in contrast to 2.5 per cent. formerly, von Eiselsberg only 0.9 per cent. to 3.3 per cent. formerly, and Neuber himself has had no cases.

71. **Expulsion of the Blood from the Lower Part of the Body.**—Momburg here reviews the thirty-four cases on record in which operations have been performed after expelling the blood from the lower part of the body by a belt applied like a tourniquet to the waist. The belt was left in place for two hours and twenty minutes in one case, but no deleterious results were observed in any instance or discovered at autopsy in the six cases in which the patients succumbed to an intercurrent affection about three months later or to the progress of the primary trouble. He insists that his technic should be closely followed, using a rubber tube about the size of a finger and four or five feet long, stretched around the body just below the costal arch; the pulse in the femoral artery should be tested at each turn of the belt. Just as this pulse disappears the ends of the tube are tied together and the ends held with a clamp. A tourniquet is then applied to both thighs and below the knees, so that by loosening these various tourniquets in turn the circulation through the lower part of the body is restored by degrees. It is even better to commence by expelling the blood from the limb by winding it upward from the toes. Then, after the belt has been applied, the bandage on the leg is removed and the leg placed lower than the pelvis, thus allowing any blood still in the pelvis to flow down into this leg, leaving this side of the pelvis practically exsanguinated.

83. **Excessive Intestinal Absorption as Cause of Constipation.**—Lipowski found that normal persons absorbed and retained from 30 to 90 c.c. of 200 c.c. of tepid salt solution gently injected into the rectum and allowed to remain for fifteen minutes, while persons inclined to chronic constipation invariably retained from 150 to 180 c.c. He calls this proportion between the amount injected and the amount absorbed the "resorption coefficient." In Fleiner's method of treating constipation by injection of oil, the main factor in the result is that the oil interferes with absorption in the intestines, and thus the feces remain of softer consistency. On account of the various disadvantages of oil, which Lipowski enumerates, he uses paraffin for this purpose, injecting it into the rectum where it spreads out in a thin layer over the mucosa, effectually preventing absorption. He asserts that it is entirely non-irritating, does not decompose, and can remain in the intestine over night, thus dispensing with the reclining necessary after taking the "oil cure" during the day. The paraffin does not generate flatus, while the laxative effect is prompter than with the oil. He has applied this treatment of constipation in 53 patients; the paraffin was injected in the morning in 46 cases and at night in the others. In every case spontaneous defecation followed after a few days, and then the intervals between the injections were lengthened and the amount reduced. He uses paraffin with a melting point of 38 C. (101 F.), mixing some with a melting point at 78 C. (173 F.), with liquid paraffin in the proportion of 1/8. This mixture is warmed until the whole is fluid, and about 200 c.c. (nearly 7 ounces) are injected through a soft bowel tube, 20 cm. (8 inches) long, the syringe being also warmed. Instead of classifying constipation as merely spastic, atonic or fragmented, he insists that the absorbing capacity of the terminal bowel must always be taken into account.

85. **Treatment of Infectious Processes with Retention of Function.**—Ritter pays tribute to Bier as having revolutionized the treatment of acute infectious processes to prevent destruc-

tion of tissue and deformity. Bier's hyperemic treatment and the more recent ferment treatment ensure healing with retention of function, a result which has assumed greater importance since the introduction of industrial insurance. Ritter then announces that the same results may be obtained by much simpler means, and reports a number of cases to sustain this assertion. All that is necessary is to keep puncturing the process while maintaining arterial hyperemia in the simplest way, which is by plunging the part into water as hot as the patient can bear it, for half an hour or an hour at a time, three times a day. He punctures every day, each time at a separate place, to avoid fistulas. The cavity fills up with serous fluid with very few pus corpuscles; the organism thus supplies its own "ferment." After the third day he punctures only on alternate days. By this means Ritter has seen suppurative processes in the neck, axilla and groin subside without leaving a trace. Encouraged with this success in eleven cases, he treated felons, suppurating affections of the knee joint, cerebrospinal meningitis, etc., all confirming the efficacy of repeated puncture as an efficient mode of treating acute suppurative processes without impairment of function. He is convinced that previous efforts to prevent reabsorption of infectious matters have been based on false premises, that the results with lowering the part, immobilization, bed rest, etc., have given good results only because they were none of them absolutely effectual in preventing absorption. Even the constricting band does not accomplish this, as the wave that follows its removal flushes out the part. It is safer to have the absorption proceed more gradually, and he thinks that a safe, simple and effectual technic has been found in the daily puncture and hot-water treatment.

89. **Stain for the Living Human Eye for Diagnostic and Other Purposes.**—Hamburger announces that he has been experimenting for nearly a year with internal administration of fluorescein which discolors the tissues as in jaundice without harm, as the effect soon disappears. In the dose of 1 gm. (15 grs.) per 25 pounds of body weight, the stain does not discolor the healthy human eye or at most not until after two or three hours, while if the eye is inflamed or diseased it is discolored almost at once. The effect is most striking when only one eye is affected. He explains this as owing to the peculiarly slow and quiet intraocular metabolism of the human eye in physiologic conditions, while all this is totally changed with the onset of inflammation. The inflammation must be true intraocular irritation to attract the stain; mere conjunctivitis does not cause the discoloration, nor the mere presence of a foreign body. The results are interesting for physiologic study of the eye and also for diagnosis of ocular inflammation.

90. **Quantitative Tests of the Pancreas.**—Wynhausen has found that it is possible to estimate the functioning of the pancreas by quantitative determination of the diastasic and tryptic ferments in the stool. He used the Wohlgemuth and Fuld technics and reports the details of several cases demonstrating the precision and reliability of this method of testing pancreas functioning.

95 Diagnosis and Treatment of Glaucoma. O. Haab.
96 Obstetrics and the General Practitioner. A. Gœnner.

92. **Suprarenal Treatment of Osteomalacia.**—Stocker reports what he thinks is the first case of non-puerperal osteomalacia treated with adrenalin. Slight improvement was evident about the sixth injection, but it proved transient, and recurrence of severe symptoms compelled castration, which proved promptly successful. One ovary was found in cystic degeneration, the other was enlarged and adherent. He tabulates the details of twenty-two other cases of osteomalacia treated with adrenalin that have been reported, the results demonstrating that in each of the 14 cases in which improvement was observed, a turn for the better was evident after the first or second injection.

93. **Bolus Alba in Tropical Dysentery.**—Frei quotes with approval Sahli's remark that the old text-books ought to be saved, as they contain many things which we throw aside in our eagerness for the new, but which time may bring into favor again, and he cites bolus alba as an instance of this foolish discarding of an extremely useful remedy. He has found it rapidly effectual in treatment of diarrhea in adults and children. In a case of tropical dysentery which had resisted all kinds of treatment and dieting for months, in the hands of a number of eminent clinicians, and had reduced the young woman to a skeleton, a prompt change for the better was observed under bolus alba treatment, and complete cure soon followed and has persisted for nearly a year to date. He gave the bolus alba according to Stumpf's directions, suspended in water, 50 gm. in 200 c.c. water, and nothing was eaten for eighteen hours afterward, but the patient was allowed to drink freely and at the end of the eighteen hours to eat a light but abundant meal. Four hours later another dose was given and the patient fasted again for eighteen hours. This was kept up with smaller doses of the bolus two or three times a day with regular meals. The diarrhea was arrested by the third day of treatment and improvement in the general condition proceeded at a rapid pace, but the patient was advised to take 10 gm. of the bolus daily for another month, and was soon in good health, weighing 140 pounds.

94. **Eyeglasses and Astigmatism.**—Dutoit warns that no one except an expert ophthalmologist should prescribe glasses when there is any suspicion of astigmatism, but he asserts that special skill is not required to prescribe glasses for simple myopia, hypermetropia and presbyopia if care is taken to avoid overcorrection.

104 *Research on Experimental Lead Poisoning. (Untersuchungen bei experimenteller Bleivergiftung.) P. Schmidt.

101. **Tympanites in Infectious Diseases.**—The clinical and experimental evidence on hand seems to indicate, Krönig declares, that the tympanites observed in the course of an infectious disease is not the expression of a complicating intestinal disturbance, but merely the consequence of the general intoxication. The rapid subsidence of the meteorism after the crisis in pneumonia speaks in favor of a toxic influence on the central organ rather than of any special toxic action on the intestines or their innervation. Compare, for example, the slow and tedious subsidence of toxic affections of the myocardium or of a postdiphtheritic polyneuritis with the prompt recuperation of bowel functioning after the crisis in pneumonia. The rapid, superficial breathing in an infectious disease is favored by the upward displacement of the diaphragm; the reaction occurs differently in women, with their soft, yielding abdominal walls, than in men with powerfully developed abdominal muscles. In men even a slight development of gas has a tendency to push up the diaphragm to a dangerous extent. In any event, this toxic tympanites in infectious diseases is extremely important, requiring treatment as imperiously as beginning heart weakness. Treatment must aim to prevent development of intestinal gases and to expel those already formed. Besides dietetic measures to prevent formation of gases, and purgatives, enemas, and especially repeated introduction of a soft bowel tube, leaving it long in place, to promote the passage of flatus, the administration of strychnin is important as a means of re-enforcing the other measures to restore tone to the intestines. Physostigmin has not fulfilled

the anticipations roused by its action in tympanites of other origin. It has failed completely in a series of cases of this toxic meteorism, but its property of stimulating to spasmodic contraction when the bowel is relaxed under the influence of atropin encourages further trials of it. Experimental and clinical experience seem to conflict here.

104. **Experimental Lead Poisoning.**—Schmidt concludes from his research that the lead keeps up a constant wandering through the body until its final elimination, and that the leucocytes play the most important part in the defensive processes against it. Consequently, the organism is better protected against lead poisoning when there are large numbers of leucocytes. The conditions and indications in metal poisoning, therefore, approximate those in infectious diseases.

108. **Sudden Death and Indications for Operative Treatment of Pulmonary Embolism.**—Busch states that of the 878 fatalities among the 9,727 patients in Körte's surgical service at Berlin during the last four years, 22 of the deaths occurred suddenly and the symptoms indicated pulmonary embolism. He has been investigating the records of this group of 22 sudden deaths to determine whether the embolus could have been successfully removed. In 12 cases, death occurred instantaneously, and yet autopsy in 7 of the 12 revealed embolism in 4, the findings very similar to those in the more protracted cases of embolism. In one case a thrombus about 7 cm. long, about the size of a pencil, was found at the bifurcation of the pulmonary artery and it could have been readily removed. The Trendelenburg operation is indicated, therefore, in such cases when conditions are favorable for immediate operation. In 10 other cases the syndrome of the embolism persisted from ten minutes to three hours before the fatal termination. Autopsy revealed embolism in 6 and conditions would have been favorable for operative intervention in 5 cases. In 4 others the assumed embolism did not exist; these 4 patients were about 50 and 70, and were being treated for a broken arm or femur or ovarian cyst, with no threatening symptoms of heart trouble. A syndrome characteristic of pulmonary embolism suddenly developed in the midst of apparently complete well-being, and death followed in from ten to thirty minutes and autopsy disclosed merely brown atrophy or fatty degeneration of the heart. In the 6 cases of positive findings the embolus extended to the remotest ramifications of the artery in 1, but in others the embolus was short and straddled the bifurcation or was loose in the left branch of the artery. In 3 other cases the typical syndrome of embolism developed suddenly in patients between 47 and 58 after an operation for gallstone or pyloric stenosis or inflamed varices on the legs. An operation was debated, but under intravenous digitalis and subcutaneous camphor and caffein the heart action grew stronger and the embolism tempest blew over, but in the oldest patient, with the pyloric stenosis, signs of gangrene of the lungs developed in a few days to which the patient succumbed; the embolism gangrene involved nearly the whole of the left lower lobe. Körte advocates in case of the onset of the embolism syndrome, morphin to tranquilize the respiration, then a preparation of digitalis injected into a vein while all is made ready for an operation which then follows if these measures fail to improve, unless contraindicated by the general condition.

112. **Importance of Hypersecretion in Origin of Pyloric Stenosis in Infants.**—Engel reports from Schlossmann's pediatric clinic at Düsseldorf two cases of typical stenosis of the pylorus in infants in whom the stenosis syndrome had probably been preceded by a phase of excessive secretion of gastric juice—actual gastrosuccorrhea. As he believes that "psychic gastric secretion" is out of the question in infants less than a month old, the discovery of large amounts of gastric juice in the empty stomach is, he asserts, necessarily pathologic. He accepts it as proved that hypersecretion alone without hyperacidity is able to induce spasmodic contraction of the pylorus. The stenosis is purely spastic at first, as evidenced by the previous unrestricted passage of fluid. Under the influence of the spasmodic contraction the pylorus becomes more or less hypertrophied, so that after the subsidence of the hypersecretion and of the spasmodic contraction the lumen of the pylorus is left a little smaller and several weeks may elapse before entirely normal conditions are restored. This assumption of the primary importance of the gastrosuccorrhea explains all the features of pyloric stenosis in infants. In both of the cases and in others in the literature small intercurrent hemorrhages occurred in the stomach, the presence of the blood inducing such profuse secretion of gastric juice that violent paroxysms followed. In one case the child vomited forty times in twenty-four hours and in the other, in which the hemorrhage was very small, the child vomited ten times in a few minutes and 50 c.c. of the stomach content were aspirated almost at once. His cases are instructive, as in both feeding was exclusively by way of the intestines, the stomach being entirely excluded. He is inclined to accept a nervous disturbance as the basis of the whole trouble—an isolated secretory anomaly.

116. **Non-Operative Treatment of Cardiospasm.**—Makkas reports two cases of severe cardiospasm in young men, with extreme dilatation of the esophagus, the symptoms having been in evidence for nearly three and five years, respectively. Both patients were cured by gradual dilatation of the cardia with Gottstein's sound, which consists of an inner and outer rubber bag with an inelastic thick silk interlining between the two. The bag is introduced and then filled with water, the soft even pressure of the spindle-shaped distended bag effectually combating the spasm. Gottstein has reported five cures in seven patients thus treated.

126 Medical Certificates. (Ue[illegible] und Gutachten.) T. Rumpf.

121. **Infiltration Treatment of Sciatica.**—Bum reports that more than half the patients were cured by the infiltration technic in 308 cases in his practice during the last four years and a half. The proportion was 52.2 per cent. cured and 23.9 per cent. improved in the 46 subacute cases, and 63.5 per cent. cured and 19 per cent. improved in the 228 chronic cases, the duration of the sciatica ranging from four weeks to seventeen years. The duration of the affection did not seem to influence the effect of the infiltration treatment, and the cure was permanent, the patients being absolutely free from pain for months and years without any efforts to spare the limb. He

never applies this treatment in the acute cases, as recent neuritis yields to bed rest and medicinal or physical diaphoresis. The infiltration technic aims to detach, without the knife, the perineuritic adhesions that have formed around the formerly inflamed nerve. If the result is not realized in one sitting, the injection should be repeated two or three times. He uses plain physiologic salt solution, injecting from 100 to 120 c.c. at once under strong pressure, the patient in the supported knee-elbow position, the cannula, 1.8 mm. in diameter and about 10 cm. long, introduced at the point on the thigh where the long head of the biceps is crossed by the lower edge of the gluteus maximus. The needle is introduced for about half its length and then the proximal end is lowered, while the needle is pushed slowly in for about 3 cm. farther. This brings the point to the sciatic nerve and the injected fluid pours into the nerve sheath, breaking up adhesions and setting the nerve free. He never made more than four injections in any case. Recurrence was observed in 4.7 per cent. only.

129 Morphologic Behavior of Minute Glands Encircling the Nipple. (Morphologisches Verhalten der Montgomeryschen Drüsen.) K. Natanson and W. Goldschmidt.

127. **Supravaginal Resection of Cervix.**—Werth compares the technic and ultimate outcome in six cases of elongated cervix requiring operative interference treated by the old technic and six treated by a new method, of which he gives an illustrated description. The unduly long cervix is resected above its implantation in the vagina, working through a median incision in the anterior roof of the vagina. The stumps are sutured together with catgut through the entire thickness of the cervix wall.

139. **Application of Cold to Back of Neck to Relieve Congestion in Nose.**—Muck has been making practical application of Winternitz' suggestion to influence the lumen of the vessels by reflex action from cold or heat applied locally to the skin. He has found that cold water poured over the back of the neck or a cold douche applied for a few seconds has a decided influence in relieving congested conditions in the nose and also bronchial asthma if it is due to a nasal reflex. He ascribes the result to the direct action on the vasomotor and respiration centers; the same effect is not realized by application of cold elsewhere to the body nor by mere application of cloths wrung out of cold water. The mechanical stimulus of the pouring water seems to be an important element in the relief experienced. Before dressing in the morning the simple application of the cold douche to the back of the neck gives great relief in chronic simple rhinitis and is liable to relieve the suffocation in asthma.

140. **Abdominal Operations in Country Practice.**—Paysen relates a number of incidents from his experience to show the necessity for immediate operation on the spot in many cases of incarcerated hernia, etc., the patients owing their lives to his prompt intervention, and he urges the country practitioner not to hesitate to undertake such at need without temporizing.

146. **Operation for Femoral Hernia Through the Inguinal Canal.**—Frank's technic is instructively shown in ten illustrations. The sac is drawn out through the inguinal ring, ligated and resected, the ends of the ligature drawn out through the muscles some distance above, where they are tied. The tendency to hernia is then corrected by suturing the posterior margin of Poupart's ligament to the pectineal fascia and the periosteum of the horizontal branch of the pubis, followed by passing four threads through the triangular ligament drawing it up to the muscles above.

147. **Roux' Nail Operation for Femoral Hernia.**—Roux fastens with a double-pointed nail the edge of Poupart's ligament to the horizontal ramus of the pubis as a radical means of curing femoral hernia, and Hochenegg has applied this technic in 38 cases of femoral hernia since 1904, all but 8 in women, general anesthesia being used in 33. The ultimate outcome in 28 cases is known, the interval ranging from six months to four years. The results have been satisfactory in every respect, even in one case in which the nail was felt to be loose. The outcome compares favorably, he considers, with other methods, while the simplicity of the operation commends it for certain cases.

148. **Preserved Human Milk for Infant Feeding.**—Rosenfeld regards Mayerhofer and Pribram's suggestion that human milk can be preserved and used for artificial feeding of feeble new-born infants as a great advance, provided that the production is restricted to hospitals and asylums and kept under strict medical supervision. The milk is drawn with a valve breast pump, described in these columns May 29, 1909, page 1803; this simulates the intermittent sucking of the child and the breast responds by yielding all its milk. Nearly 3 ounces can thus be drawn in a few minutes. The breasts seem to secrete more milk as more demands are made on them, so that the women's own children do not suffer from loss of the extra amount drawn. He calculates that the three or four maternities at Vienna, with an average of 120 parturients, could easily supply about 20 quarts of fresh breast milk a day for this purpose, ample to supply 50 feeble new-born with the life-giving fluid. In order to keep a sufficient supply on hand, the mixed milk is sterilized by the Budde process, that is, addition of a small proportion of hydrogen dioxid as the milk is heated to a moderate temperature, not over 55 C. in

the water bath. This sterilizes it completely while not impairing its vital properties, taste or aspect, according to experiences reported by Escherich and others. Infants fed on breast milk thus prepared and kept until needed seemed to thrive excellently, in every respect as if fed directly from the breast. The main point, Rosenfeld emphasizes, is to keep this milk supply out of commercial hands, as it should be a strictly medical affair.

menti [illegible] ei [illegible]
negli [illegible]elizlani.
161 *Gastric [illegible] Test. (Carcinoma gastrica e prova di Salomon.) G. Alessandri.

155. **Stricture of the Female Urethra.**—Cuturi concludes his study of the treatment of stricture by emphasizing that the dilatation must act dynamically, not mechanically. Extreme gentleness is necessary. In a hemophilic patient he found it possible to prevent recurrence of hemorrhage from introduction of the sound by previous instillation of 2 per cent. silver nitrate. Traumatic and obstetric stricture requires internal urethrotomy, as dilatation is ineffectual in callous tissue.

156. **Chloroform and Helminthiasis.**—Barnabo was performing a laparotomy in a young women when severe retching was observed with acute suffocation and threatening syncope. Opening the patient's mouth to make traction on the tongue, the tip of an ascaris was seen in the throat and prompt recovery followed its removal. Two others were vomited about six hours later, after which recovery was uneventful. He was present in another case in which fatal suffocation from worms occurred during chloroform anesthesia, and thinks it possible that some of the "chloroform deaths" on record may have been due to unsuspected worms. He now makes a practice of inquiring before operating whether the patients have known of the presence of helminths. His patient told him afterward that she had passed some helminths shortly before. If he had been aware of this he would have postponed the operation until after a course of worm medicine. He thinks that the chloroform is responsible for the migration of the helminths.

161. **Gastric Cancer and the Salomon Test.**—Alessandri reports the findings of the Salomon test applied in twelve cases of stomach trouble suggesting cancer, the results being controlled by other tests. In every case of carcinoma of the stomach confirmed by the course of the affection the Salomon test gave positive findings, while they were negative when the cancer was in a neighboring organ or if the trouble was of other origin. The reaction may be positive when the ulceration is so small that its presence is not revealed by the ordinary clinical methods. It seems to be established that cancer of the stomach displays a tendency to ulcerate exceptionally early, which enhances the value of this test. The technic was described in The Journal, Sept. 12, 1903, page 694.

165 *Experiences with 206 Cases of Mammary Cancer. L. Fiori.

162. **Inguinal Hernia in Children.**—Andrei reports the operations for inguinal hernia at the Florence surgical pediatric clinic, a total of 430 inguinal hernias in 395 children, all but 38 being boys. The Bassini technic was used except in one case. The mortality was 1.77 per cent. One of the 7 children who died was a child a month old with strangulation of the hernia ten days before the operation. Inguinal hernia is congenital less frequently than is generally assumed, and strangulation is comparatively rare, while the effects are less serious than in adults at first. The experiences with 6 children operated on under the age of six months and 59 under twelve months, 97 between one and two years and 47 between three and four, confirm the advisability of operating early, as herniotomy is borne well even by very young children, and the single operation is preferable to the wearing of a truss if conditions do not permit of scrupulous care. Strangulation was observed in 14, that is, 3.25 per cent. of the total 430 hernias, and in all but 4 cases were in boys less than a year old. The tendency to strangulation and to recurrence is much less in children than in adults, owing to the elasticity of the tissues. In 16 cases the appendix was found in the hernia, but Andrei advises against removing it, if sound, at the herniotomy.

165. **Mammary Cancer.**—Fiori reviews the experiences with 206 cases of mammary carcinoma at Ceci's surgical clinic at Pisa, 1888-1908. One patient was between 20 and 25 and one between 25 and 30; 13 between 30 and 35 and 22 between 36 and 40, while only 3 were over 70. He has been able to follow the ultimate outcome in a large proportion of the cases. Among these, of the 7 patients with small tumor, nonadherent to the skin, with only a few glands in the axilla slightly enlarged, 4 are still in good health from seven to eleven years after the operation, one succumbed to an intercurrent disease, one was healthy when last heard from and one returned in a few months with an inoperable recurrence. Of the 40 with more advanced cancer, 20 are still in good health after three or more years, and of the 23 with involvement of the entire breast, the tumor adherent to the skin and pectoral muscles with ulceration or multiple nodules and metastasis, one is still alive after three years; 65 per cent. succumbed to generalization of the malignant disease and 30 per cent. to local recurrence, while 2 others were in good health after seven and seventeen months. The permanent cures in these three groups of cases are thus: 80 per cent.; 50 per cent. and 5 per cent., for intervals ranging from three to thirteen years to date. The interval between the first signs of the tumor and the operation was from fifteen days to three months in 20, and between one and five years in 52; in 5 cases there had been an indolent nodule since early life.

DIAGNOSIS OF OTOGENIC MENINGITIS

HOLGER MYGIND, M.D.
Professor of Otology and Laryngology, University of Copenhagen
COPENHAGEN, DENMARK

Until recent years, the early diagnosis of otogenic meningitis was of little practical significance, except inasmuch as it enabled the physician to prepare the friends of the patient for the fatal termination of a disease, which in its suddenness often comes as a lightning from a clear sky. But since surgical treatment has been employed in this disease, and not without success, the importance of an early diagnosis has increased appreciably inasmuch as it may indicate an operation to prevent this fatal result.

Before entering on the diagnosis of otogenic meningitis, a few facts as to the etiology may be mentioned.

Meningitis, which is according to all statistics the most frequent intracranial complication in suppurative otitis media, appears very rarely in infants under a year. It is not rare after the fortieth year, but older children and young people are those most frequently attacked.

It is generally assumed that otogenic meningitis is, in most cases, caused by a retention of pus in the middle ear. My experience does not support this supposition. I have not, as a rule, found otoscopic signs of retention in cases of otogenic meningitis, and in about half of the cases observed by me the mastoid region did not exhibit the slightest trace of infiltration or tenderness. I am, therefore, inclined to believe that the nature of the suppuration, combined with the anatomic relations of the petrous portion of the temporal bone and the mastoid process, play the most important part in the pathogenesis of otogenic meningitis.

As to the nature of the suppurative process, various observers and I myself have most frequently found pneumococci, staphylococci and streptococci as the cause of the inflammation of the soft membranes of the brain in cases of otogenic meningitis. Another fact elicited by my researches is that in most cases of otitis media causing meningitis there is a very marked *acute* osteitis of the mastoid process, even when the suppuration of the tympanum and the osteitis of the mastoid process are chronic. This easily explains why otogenic meningitis is frequently preceded by pains in the diseased ear.

Meningitis of otogenic origin is often produced through a suppuration of the labyrinth, a fact to be borne well in mind during operation. That phlebitis of the sigmoid sinus is not unfrequently the medium is also of practical importance in eventual surgical interference. Otogenic meningitis is, in other words, often combined with suppurative otitis intima and with sinus phlebitis, the two latter being often primary in relation to the meningitis. It is, however, my impression that the suppuration of the middle ear now and then spreads explosively to all parts of the cranial cavity simultaneously, thus causing two or more intracranial complications.

As to the nature of the meningitis caused by otitis media, it must be observed that the term "meningitis" is here always used as an expression for "diffuse purulent leptomeningitis." Of this disease there is, in my opinion, but one *trustworthy objective sign, viz., turbidity* of the cerebrospinal fluid, emptied by lumbar puncture, caused by overproduction of round cells. I lay much stress on this objective sign, because an otitis *media can cause all the subjective* symptoms of a meningitis and also the objective signs, especially rigidity of *the neck and the* sign of Kernig, without producing a diffuse purulent meningitis—cases which are often classified under the term of "meningitis serosa." On the other hand, a few cases are reported in literature of abscess of the brain and of phlebitis of the sigmoid sinus with turbidity of the cerebrospinal fluid, in which the postmortem examination did not reveal any macroscopic signs of purulent leptomeningitis. I consider these few cases, however, as cases of diffuse purulent meningitis, in which the meningitis has been cured prior to the death of the patient.

Symptomatically otogenic diffuse leptomeningitis may be described as an acute febrile disease with "diffuse" brain symptoms, restlessness, insomnia, irritability, alternating with drowsiness, delirium, etc. "Focal" brain symptoms are, however, very frequent, viz.:

Ocular: nystagmus—often, though of labyrinthal origin—spasms and pareses of the muscles of the eyeball (double vision, squinting, conjugated deviation).

Facial: Paralysis of the facial nerve.

Relating to the extremities: Jackson's epilepsy, hemiplegia, etc.

The appearance of "focal" brain-symptoms, caused *either by disturbances of the* circulation in the surface of the brain or by diffuse encephalitis, often gives rise to a *false supposition* of the existence of an abscess, rendering diagnosis extremely difficult.

The objective signs are: Vasomotor disturbances of the skin (pallor alternating with redness of the face, "taches cérébrales," the sign of Trousseau, hyperesthesia, etc.), irregularity of pupil action, and rigidity and contraction of groups of muscles causing rigidity of the neck and the sign of Kernig. I have, however, observed three cases of otogenic meningitis in which neither of the two latter symptoms were present, although the patients were under observation up to the time of their death.

Changes of the fundus of the eye are not frequent in patients with otogenic meningitis. In twenty-four consecutive cases observed by me only four presented choken disc or optic neuritis.

The fever is seldom low (about 100 F.); in exceptional cases there may, however, be *no rise of the temperature* in the beginning of the disease. More frequently, and especially during the onset of the meningitis, it is very high (about 104) and the affection then often assumes the appearance of an acute infectious disease (pneumonia, typhoid fever, influenza), from which it may be difficult to distinguish it. The temperature is, however, generally only moderately raised, varying from 101 to 103. Even in cases complicated with sinus phlebitis the fever hardly ever assumes a pyemic type. The pulse is generally quick, and not infrequently irregular.

Albuminuria appears now and then.

The diagnosis of otogenic meningitis is often difficult. First, it may be difficult to decide whether the meningitis is due to the otitis media present or whether the latter be an accidental complication. In such, by *no means rare, cases, the circumstance that the affection* of the brain has developed some time after the ear disease is all that speaks for a connection between the two; for, in my experience, acute suppuration of the middle ear rarely produces meningitis before it has lasted a week or more, the time in the cases I have observed varying from three days to five months. In other words, otogenic meningitis does not generally appear until after the infectious agent has acted for some time on the soft membranes of the brain. There is, furthermore, reason to believe that there is a stage of the otogenic meningitis in which the subjective and objective symptoms of the meningitis may be fully present, but in which the pathologic changes produced by the diffuse purulent leptomeningitis may be as yet undeveloped. This stage Körner, the eminent German otologist, to whom we are so much indebted for his contributions to the pathology of the otogenic intracranial complications, calls a preliminary stage (*Vorstufe*) of meningitis. I would rather suggest the term "initiatory stage of meningitis," as I include under this head only cases in which the cerebrospinal fluid has already become opalescent. This is of practical importance, inasmuch as it gives us a right to hope for a successful operative treatment even in cases where all subjective and objective signs of meningitis are developed, if only the operation is performed early.

Second, the diagnosis of meningitis in cases of chronic or acute suppuration of the middle ear is often very difficult, for otogenic meningitis may simulate or may be simulated by "meningeal irritation" or "meningismus" without any organic disease of the brain, by pneumonia and other acute infectious diseases (typhoid fever, septicemia, influenza and malaria), tuberculous meningitis and by other otogenic intracranial diseases.

True meningitis differs from the series of symptoms called "meningeal irritation" or "meningismus," i. e., the well-known meningeal symptoms often appearing in children and young persons during the course of an acute otitis media, inasmuch as meningitis generally (1) appears some time after the onset of the ear disease, (2) starts with great suddenness and intensity, (3) may exist without symptoms of retention or of mastoiditis, (4) runs its course with increasing rapidity and intensity of the symptoms (a circumstance on which I lay much stress, and which has not been sufficiently recognized), and (5) does not occur in infants, in whom "meningeal irritation" often appears.

Tuberculous meningitis differs from meningitis due to otitis, inasmuch as tuberculous meningitis generally (1) is secondary to other tuberculous manifestations, (2) begins with a preliminary stage, (3) runs with less violent symptoms, and especially with a lower temperature, (4) exhibits "focal" brain symptoms more frequently than otogenic meningitis, and (5) is very rare in persons over the age of forty.

Typical otogenic cerebral abscess differs from meningitis due to otitis in the following points: Cerebral abscess has (1) a distinct prodromal stage, (2) slower development of the symptoms; further (3), often exhibits "focal" symptoms, (4) produces slow cerebration and slow pulse.

All subjective and objective signs may, however, lead to a wrong diagnosis, excepting only turbidity of the cerebrospinal fluid emptied by lumbar puncture. I lay great stress on this procedure as a diagnostic agent, having used it in my hospital over a hundred times without ill effects, and in several cases it has been the only way in which a correct diagnosis could be obtained. A further proof of the importance of this diagnostic agent is that, in some of these cases in which lumbar puncture was dry or the fluid mixed with blood, no correct diagnosis could be arrived at until postmortem.

In cases of meningitis of aural origin the cerebrospinal fluid is more or less opalescent in the *first stage of the disease, becoming more and more milky* in appearance, and at last puriform. Under the microscope numerous round cells are always found and nearly always an abundance of polynuclear leucocytes. Bacteria are generally present, but I have seen a few cases in which no bacteria appeared even immediately before the fatal end of the disease.

Clear cerebrospinal fluid does not, however, with certainty exclude meningitis, as it always takes some time for the fluid to become opalescent. In three cases of postoperative meningitis observed by me more closely I found in one case that the cerebrospinal fluid was still normal twenty-four hours after operation, in another it was turbid twenty-six hours, and in the third thirty-six hours after.

If, then, in the first stage of meningitis the puncture yields a clear fluid, it is necessary to repeat it once or twice to be certain.

In cases of tuberculous meningitis the cerebrospinal fluid is generally only slightly opaque, often containing small flocculi of fibrin. The cells are nearly all mononuclear, and bacteria are seldom found. In a few cases I found bacteria which in the earlier stages of my experience led me to the false belief that I had to do with otogenic meningitis. Tubercle bacilli are sometimes present.

The therapeutic value of lumbar puncture is in my opinion almost nil.

Besides lumbar puncture there are two diagnostic agents of value, viz., examination of the hearing and of the static part of the labyrinth. The first examination consists in proving whether there is any hearing in the affected ear or not, total deafness speaking in favor of a labyrinthine suppuration with secondary meningitis. The best method is to apply the noise-apparatus of Barany in the healthy ear and then to examine whether the patient hears the speaking voice with the diseased ear. This method is, however, often difficult of application when the patient is a child, or when there are more pronounced brain disorders. This objection does not apply to the examination of the static function of the labyrinth. It is performed by syringing the diseased ear with cold water (50 F.); if the static part of the labyrinth is destroyed, no nystagmus is produced, while in cases in which this part is intact the eyeball makes small jerks toward the opposite side, especially when the patient's eyes are turned in that direction. The destruction of the static part of the labyrinth points to meningitis produced by suppuration of the inner ear. A functional examination of the labyrinth can also be useful in cases where both ears are diseased, the ear in which the labyrinth is destroyed being the probable cause of the meningitis.

Havnegade 31.

DISPOSAL OF SPUTUM

WILLIAM J. MANNING, M.D.
Medical and Sanitary Officer, Government Printing Office
WASHINGTON, D. C.

For some time past I have given considerable attention to the disposal of sputum, and the idea has very strongly impressed itself on me that we are altogether too careless in disposing of this dangerous factor as regards health, especially in workshops where large numbers of persons are employed and in conjunction with hotels, saloons, barber shops, railway stations, public buildings, etc.

Signs will be found displayed in almost every town and city of the United States which caution persons not to spit on the floor, but in cuspidors, even invoking legal penalties for failure to observe the injunction. Yet the methods for the disposal of the contents of these receptacles are very faulty in a good many instances.

Persons with incipient and ill-defined cases of tuberculosis, as well as those suffering from this disease in its later stages, during their daily ambulations and at work at their respective vocations, use the same cuspidors to receive their expectorations as those used by uninfected persons, making the handling and disposition of the sputum a constant and ever-present source of danger to the cleaner (see high mortality from tuberculosis among servants in census reports), as well as to the community in which the factory, hotel, or public building is situated. The observing person will find that these vessels are cleaned near drinking-water places, or roughly dumped on the streets or yards adjacent to such buildings, or in the respective basements or cellars connected therewith.

The type of cuspidors in use at the present time in the great majority of cases appear to be faulty, very little attention evidently having been paid to ease and thoroughness of cleaning. The principal fault in the majority of this type and class of vessels on the market is the undercut found just below the constriction or neck. It is at this point that expectorations are received on the inner flare or side of lip; they run under this shoulder or undercut and remain lodged or fixed there. The repulsiveness of the cleaning operation almost prohibits the cleaner from placing his hand or even a sponge under this point for the proper removal of expectorations.

While, of course, the moist tubercle bacillus can not be readily transported by currents of air, yet it is viable and sooner or later dries in one manner or another, and is easily transported.

While breaking into several parts a number of cuspidors constructed along the lines of pattern shown in Figure 2, which were picked up in various quarters of cities, I found incrustations in some instances one-half inch in thickness, and from a dry to a semi-solid consistency, but, without exception, all in a putrid condition, and furnishing a most fertile culture media.

In designing the type of cuspidor shown in Figure 1 and now adopted by this branch of the government I have tried to avoid all the objectionable features found in the older styles, of all shapes, some of which are very ornate, but all showing, more or less, that very little thought had been given to the proper and thorough cleansing of such receptacles.

The sharp flare or lip shown in Figure 1 is intended for quick drainage into solution placed within vessel and hereinafter described. Sufficient constriction has been left at the neck partially to hide the contents in the cuspidor for esthetic reasons; yet the opening permits all parts of the vessel to be placed under observation as to thoroughness in cleaning.

The undercut or deep shoulder has been avoided in the type shown in Figure 1, which permits easy, rapid cleaning with a cotton dish-mop and boiling water in the absence of special facilities for such specific cleaning. The bottom of the cuspidor shown in same figure is slightly convex and in continuity with the round sanitary corners or coves, all with the special object in view of self-draining and easy, effective cleaning.

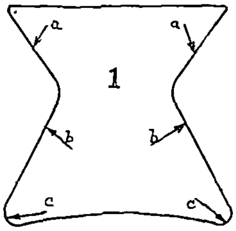

Fig. 1.—Self-draining sanitary cuspidor. Note sharp flare (a) to drain quickly, absence of undercut (b), and rounded corner (c) continuous with convex bottom.

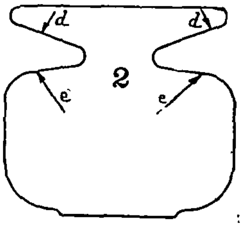

Fig. 2.—Insanitary cuspidor. Note flat flare (d), which is slow in draining, and sharp undercut or shoulder (e).

In the general system that has been adopted, illustrated, and presented herewith the cleaner picks up the soiled and infected cuspidors from the floors of the work-rooms in a nested fashion five at one time, after a manner shown in Figure 3, by a specially designed sanitary lifter or clutch, made of two pivoted members surrounded by a guard and surmounted by a handle and a simple locking device to relieve the constant pressure of the hand when the loaded lifter is to be carried any distance. The idea of this device was first conveyed to me by the obstetrical forceps, from which it is an evolution, so to speak.

The cuspidors are then carried by the same lifter to a box truck, shown in Figure 3, which is lined with galvanized sheet iron, and are deposited, still nested, between gas-pipe standards that are threaded and screwed through the bottom of truck to ensure rigidness, such uprights preventing the tipping of vessels, and also permitting the easy entrance of the lifter to pick up five sterilized cuspidors contained in same truck, at the same time that the five infected or soiled vessels are deposited. This permits their being laid down or distributed by the same instrument in the place of those picked up, serving, additionally, as a time-saving procedure.

After the trucks are filled in this manner, on each floor, they are wheeled to a freight elevator and dropped to the basement, where is situated the sterilizing chamber, shown in Figure 4.

The truck is wheeled directly into the chamber and up near the edge of trough; the side of the box truck is then removed, and the operator, as shown in Figure 4, seizes the lip or flange of the soiled and infected cuspidor with a short pair of hand forceps, lifts the vessel clear of the gas-pipe standards fastened to the bottom of the truck, and plunges the cuspidor into the boiling water in the trough, and, at the same time, with a pronation of the forearm, overturns the vessel *under* the water.

By this method the entire contents escape into boiling water, which cooks or coagulates the albumin in the micro-organisms, if such be present, and at the same time renders sterile other material before passing through the outlet, which is simply a pipe, surmounted by a wire tripod, between the wires of which boiling water flows constantly, and which thus permits the easy escape of all material under 1½ inches in diameter, but stops banana-skins, apple-cores, etc., that would otherwise clog the pipe leading to sewer, which is 3 inches in diameter.

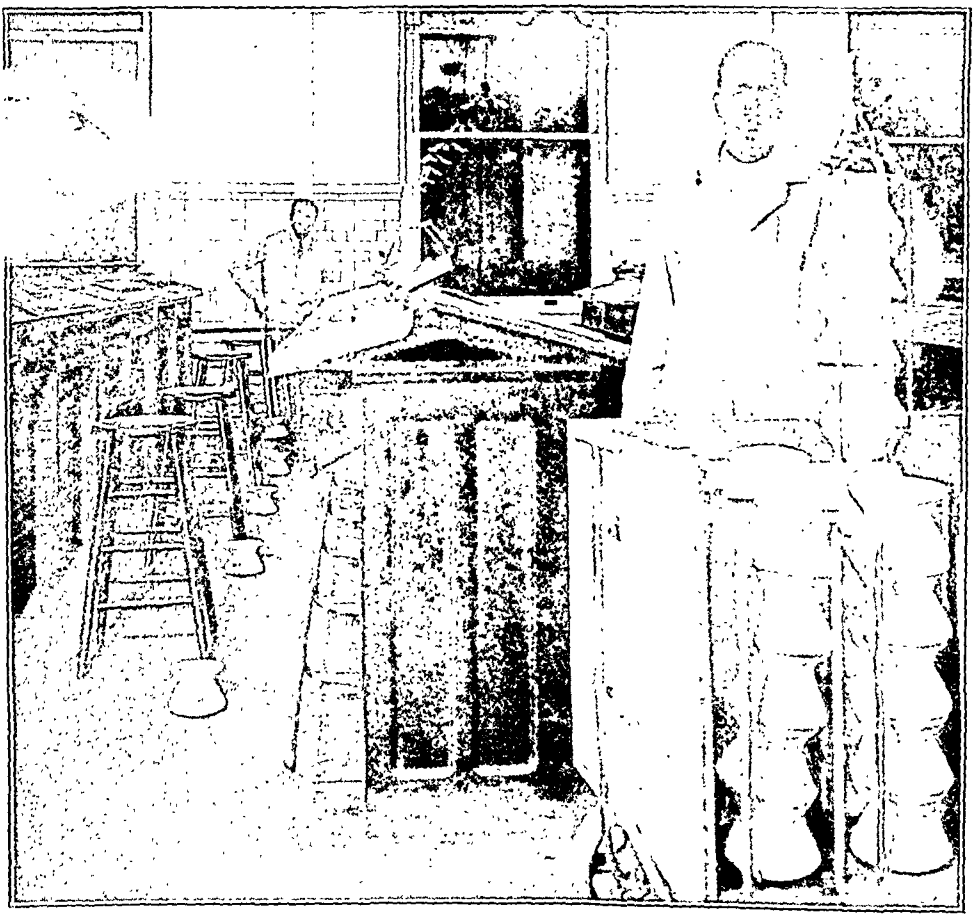

Fig. 3.—Method of collecting cuspidors from floors of workrooms.

Still grasping the flange or lip of cuspidor after it has been overturned in water with the short forceps before described, the operator swings the now upright and roughly cleaned cuspidor forward under a jet of live streaming steam, which is released by pressure on a foot tread, the posterior part of which is connected with a chain to a lever in the side of an inverted steam whistle valve which it controls, and which promptly closes the instant the pressure of the foot is removed from the tread, thus shutting off the jet of steam in an automatic manner. Figure 4 shows the first cleaner and this mechanism in action; and at the rear end of the trough the other cleaner is shown, who has completed the procedure just described and is about to thrust the now sterile cuspidor into rack clutch, still grasping the short forceps containing cuspidor. When sticky or tenacious material persists in clinging to vessel and the jet of steam fails to dislodge the débris, it is instantly removed by a hand dish-mop suspended by chain to rack and which is allowed to fall back in the boiling water after it has been applied by the other hand of the cleaner to remove substance on surface of cuspidor. The mop is therefore always sterile, within easy reach, and readily picked up by the chain attached to the handle (R) by the disengaged hand of the cleaner.

In Figure 5 the truck is being refilled by one cleaner, who is plucking the thoroughly washed and sterilized vessels from the spring clutch on the rack for this purpose. As each layer is placed in the truck previous to its transmission back to the work-room the other cleaner is pouring, from an ordinary hot-water can, a solution of potassium permanganate of a strength approximately 1 to 2,000 into each cuspidor, to the amount of four ounces, where the solution remains until the vessels are next cleaned at the termination of each eight-hour shift, and thus receives and disinfects the sputum between stated cleaning periods.

At first I used a solution made up for this purpose of corrosive mercuric chlorid 7.3 gr., citric acid 7.7 gr., cosin coloring q. s., to each gallon of water, giving a strength of approximately 1 to 8,000. The mercuric chlorid was used, of course, for its germicidal properties, the citric acid[1] to retard the coagulation of the albuminoid substances found in expectorations and to prevent the formation of insoluble albuminates, thus permitting the bichlorid to permeate the mass more thoroughly. The cosin was used simply for purposes of differentiation from harmless liquids for safety in handling.

Fear of persons drinking the solution with suicidal intent and of cases of accidental poisoning among the cleaners, however, caused me to substitute potassium permanganate 1 to 2,000 as a cheap, practical, nontoxic, easily prepared, odorless disinfectant, as well as a germicide, in lieu of the former solution. I still use the bichlorid, however, in the strength of 1 to 1,000 to scour water-closet seats at the end of the day's work, and in the form of a spray of the same strength on the floors after the latter are scrubbed, allowing the solution to dry out with the damp floors. This method is better than to use the bichlorid in the wash-water, where it is precipitated as chlorids, *owing to the dirt*, etc., in the water.

---

[1] Egbert in his text-book on hygiene was the first to draw attention to the use of this agent in preventing rapid coagulation of albumin.

The Government pays but 14 cents per pound for the potassium permanganate salts, and ten pounds only are used for an entire year's supply for the purpose mentioned in the building, where upward of 4,500 persons are employed under one roof. It is made up in a fresh state each night in the cans shown in illustration.

The expense and the possible objection to its pungency renders the use of formalin in a large way impracticable. Saturated solutions made up of chlorid of lime, while cheap and efficient, are objectionable on account of the odor. Solutions of carbolic acid, strength 1 to 40, are objectionable on account of odor and toxic properties in any buildings aside from institutions and hospitals. Yet, as is well known, all are efficient and practical if suitable and indicated by each particular instance.

While a great many patented antiseptics are on the market together with proprietary preparations *with high-sounding*, euphonious titles, the majority of them are expensive and mask the indications of putrefaction by their own particular odors, and do not always remove the cause. Their effectiveness, for this reason, in a good many instances is questionable.

Experience in dealing with the different temperaments and idiosyncrasies of a large number of persons gathered together for stated periods of time each day has taught me that it is a very difficult matter to please all, especially as concerns odors, although there may be no real basis for complaints.

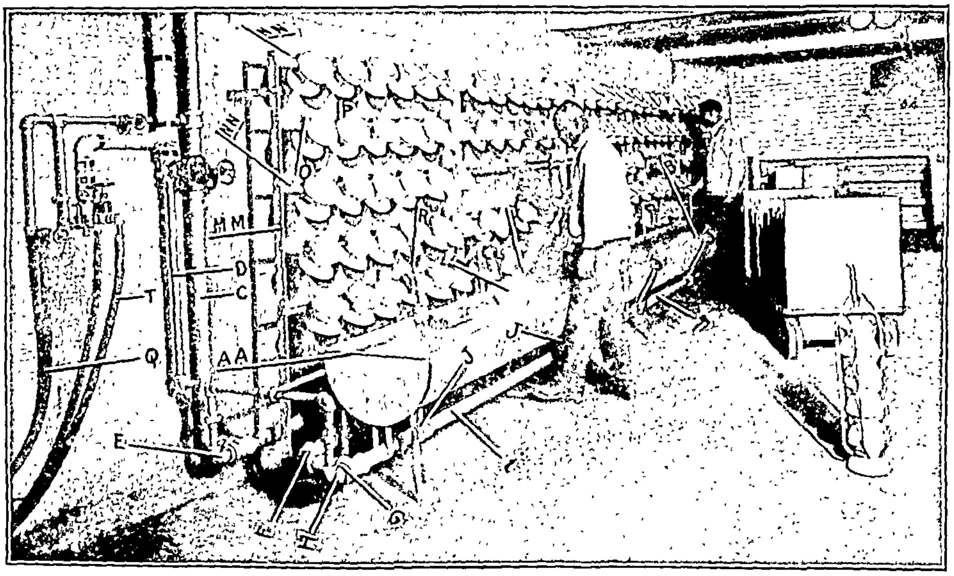

Fig. 4.—Sterilizing chamber in basement and method of unloading trucks together with procedure in washing and sterilizing the soiled and infected cuspidors. (See text for explanation of the apparatus.)

The general view of the sterilizing chamber shown in Figure 4 will be here dwelt on to some extent regarding details. The galvanized iron trough (AA) is made up of 22-gauge galvanized sheet iron, the sections being riveted together and all joints soldered. It is smaller at the fore end to permit of easy drainage toward the opening for the pipe (B) leading from the trough to the sewer. The trough rests on band iron strips, cradle fashion, terminating, on each side, by an extension bent at right angles, forming a web foot that is embedded in the cement floor after being secured by expansion bolts that ensure rigidness. The cold-water pipe (C) leading from the street main is placed at the end of the trough leading down from the wall of the room. Running parallel with it is one-inch steam-pipe (D). At the point marked E, by means of a ⅜-inch nozzle, the stream of cold water is mixed with steam, which raises the temperature to about 110 F. The then heated water continues on its way, and, by means of a short turn or bend (F), some three feet in extent, makes its return to point G, whence the partially heated water is again mixed with the jet of steam from the ⅜-inch nozzle (H), at once raising the temperature to 212 F., or the boiling point of water. This method avoids the *noise and "knock" of a direct jet of steam thrown into* a body of water. It produces boiling water in from six to eight seconds, and maintains it always at the boiling point. Nozzles are within the pipes mentioned.

The boiling water continues along the pipe (*i*) and emerges through the pipes marked JJ up into the trough by a fountain effect (K). As the water, by street pressure only, is thus forced up, the "wash" penetrates through a wire-mesh soap-pocket placed against the inner side of the trough (which does not show in the illustration), wherein is placed a bar of common washing soap, which procedure results in soap-suds with boiling water.

At the rear of the trough is placed a rack (MM) constructed of angle-iron or made of sectional gas-pipe, as the case may be, supported by vertical braces, in addition to parallel cross-pieces (NN) placed 14 inches apart, and perforated by holes every 10 inches, through which pass ⅛-inch flat-headed carriage bolts, running through the eye of the rack clutch (O) and secured by nuts on top of the cross-pieces (P). The rack clutches are made of ⅛-inch steel spring wire and are held rigid by a bolt through the eye formed by twist in loop of spring or clutch. Figure 4 shows one operator about to thrust a vessel into the clutch, which expands to receive it and then contracts around the constriction or neck holding cuspidor firmly, mouth down, for drainage. The vessel dries very quickly by evaporation owing to heat imparted to cuspidor by the boiling water.

The rubber hose at the point marked Q is utilized for flushing the trough after the cuspidors have been cleansed and for freeing the bottom of the trough from tobacco quids, débris, etc., and such sediment as remains after water has been allowed to drain through the waste outlet to the sewer controlled by a valve; the short pipe (B) with wire tripod being removed to allow the trough to drain flush to belly of bottom. The hose (T) is used to "blow" or conduct live, streaming steam in sterilizing inside of empty trucks before reloading, previous to transmission back to floors.

The trough in the sterilizing chamber and the hose (T) are also utilized in washing and sterilizing garbage-cans, some forty-five in number, placed at various points on floors of building to receive litter, food débris, fruit-skins, etc., of the employés. The cans are specially made of heavy galvanized steel, 20 gauge, with tightly fitting covers and convex bottoms to permit easy cleaning, and otherwise so constructed that the base of each can is smaller than the top or mouth, which permits their nesting within each other to aid rapid collection and to save space upon flat truck that can be made to hold twenty in the manner described but only four if the cans did not permit nesting.

Each day, just after lunch, a cleaner starts at the top floor of the building with truck and drops from floor to floor by means of a freight elevator and collects the cans at the various points by wheeling the truck near their respective positions to expedite and permit easy handling.

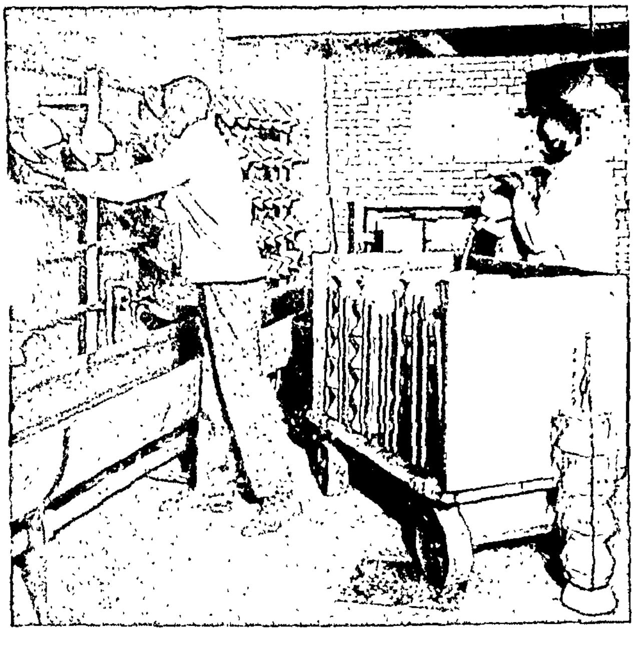

Fig. 5.—Method of placing solution in cuspidors and reloading trucks.

The cans are then roughly cleaned by being wheeled to and the contents being emptied into the crematory, again "nested," and taken to the trough in the sterilizing chamber, where they are immersed and washed in boiling water by means of a sawed-off mop-handle and floor mop, which I have found to be very practical for this purpose. Each can is then removed in turn from the trough and placed under the hose (T), which conducts live, streaming steam into each can by means of the manipulation of the hose by the cleaner. The cans are then nested again and removed back to floors. This method leaves a can cleanly and without disagreeable odor.

The cans are numbered consecutively and lettered for respective floors in red lead paint that withstands obliteration from the action of boiling water and repeated washings.

The floor of the room is composed of cement, graded toward the center, at which point is placed a cesspool trap, which permits rapid self-drainage and drying after the floor is flushed with hose (Q), and which is connected with sewer, thus insuring neatness and cleanly conditions.

Fourteen hundred cuspidors of the pattern shown in Figure 1 are washed and sterilized in the manner hereinbefore described at the termination of each working shift of eight hours.

Many of the employés use tobacco, which excites salivation, and their duties are of a sedentary nature and within a comparatively small one of floor space, which explains the great number of receptacles required.

Previous to the introduction of this method, about one year ago, sawdust spit-boxes were used, but they were insanitary and very dirty from the fact of the sputum collecting or "caking" on the sides, and the cleaning was very difficult, dangerous, and inefficient. Some idea of the magnitude of this work may be gained when the fact is stated that under the old system 400 barrels of sawdust were used each month, at a total cost of $100, to receive the sputum in the boxes.

The system appears to have its educational features along hygienic lines also, and, aside from promoting the health of employés, teaches, by practical illustration, a lesson in hygiene as to the care taken and of the danger of contact that must of necessity leave its impress on those observing its work, for it will be noticed that with the exception of the period during which the cleaner plucks the sterile vessel from the rack for purposes of reloading, as already described (Figure 5), the whole procedure from beginning to end is accomplished without digital contact. The educational feature mentioned was always before me while evolving the system, and served, in a measure, as a stimulus.

While, of course, the conditions shown by pictures of the sterilizing chamber are almost ideal, as befits a great government institution, yet without a special room a splendid substitute can be obtained in the corner of any basement in factory buildings, hotels and public buildings elsewhere in the United States at the cost of a few dollars, for it will be noted that the fittings and equipment are very simple.

It will give me great pleasure to answer any question pertaining to further details in reply to those persons who might be interested, after reading this article, in fitting up similar systems in their own factories, workshops, and public buildings by their own plumbers and steam-fitters, and I have given considerable space to complete details with that object in view.

While at the onset there were many prejudices and opposition to things new and which had to be overcome when I first broached and explained the method, yet by the special gold medal awarded this bureau for the exhibit of sanitary cuspidors, devices, and methods at the International Congress on Tuberculosis I have been amply and fully repaid for any thought, work, or experiment given on my part as concerns the system.

1248 Eleventh Street, N.-W.

Abuse of Heart Tonics in Valvular Lesions.—J. V. Montenegro of Madrid publishes an article in the *Siglo Medico*, May 8, 1909, laying down the principle that iron should be given in valvular lesions of endocarditic origin and iodid when they are due to arteriosclerosis. Many treat them all alike, however, giving digitalis at once, without stopping to analyze the cause of the disturbances. He urges the general practitioner to beware of such abuse of heart tonics, advising him to use iron or potassium iodid according to the above indications while studying the case further, and to give the digitalis intelligently if at all.

THE SURGICAL TREATMENT OF CERTAIN DEFORMITIES OF THE JAW ASSOCIATED WITH MALOCCLUSION OF THE TEETH*

W. WAYNE BABCOCK, M.D.
Professor of Surgery in the Temple University and of Oral Surgery in the Philadelphia Dental College
PHILADELPHIA

With the development in orthodontic practice it is surprising that so little advance has been made in the surgical treatment of prognathism, receding maxilla and other marked deformities of the jaw producing malocclusion. In the main the text-books on oral surgery contain no reference to the subject and little is to be found in modern treatises of surgery. In Von Bergmann's elaborate "System of Surgery," however, four lines relate that in a successful attempt to improve the deformity of a receding chin, Von Bergmann made an extensive resection of all of the processes, including the coronoid process, and subsequently displaced the entire jaw by the aid of an artificial dental apparatus.

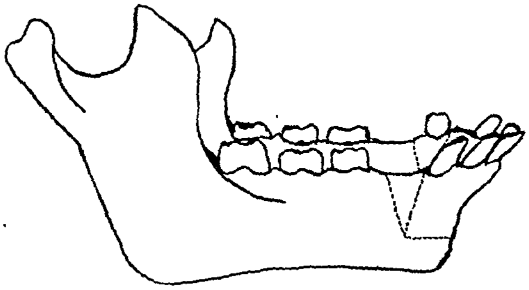

Fig. 1.—Diagram showing the osteoplastic resection of the lower jaw performed by Hullihen, July 12, 1848. The dotted lines indicate the lines of bone division with the saw. The triangular sections were removed from each side and the mobilized anterior segment of the jaw tilted back into occlusion.

HISTORY OF THE SUBJECT

Over sixty years have lapsed since Dr. S. P. Hullihen,[1] of Wheeling, Ga., successfully devised and performed an osteoplastic resection of the jaw, yet the modern works on dental practice and orthodontia mention but a single operation, and that similar in principle to this one of antebellum days. Dr. Hullihen's patient, a girl of 20, had an eversion of the lower lip with elongation of the lower jaw and protrusion of the process and lower incisors from the constant traction of a scar from a burn of the neck received fifteen years previous. Although an unsuccessful attempt to improve the condition had been made by two surgeons in New York City, Hullihen, without anesthetics, at a time when hemostatic forceps and antiseptics were unknown, boldly resected V-shaped sections from each side of the jaw, the section on the left side including the bicuspid. The V-shaped sections extended two-thirds of the way, through the bone, the apices being below. From the apices of the incisions the saw was turned horizontally forward, completing the section and leaving the upper two-thirds of the anterior portion of the mandible attached to the soft tissues only (Fig. 1). The removal of the V-shaped sections of bone permitted this loosened portion of the jaw to be pushed back, securing occlusion with the upper teeth (Fig. 2). From an impression taken in soft wax a silver plate was struck up which when applied held the section of the jaw in proper position. After this operation the tissues rapidly healed and Hullihen later transplanted a large flap of skin from the shoulder and upper arm to the neck to enable the head to be raised, and finally, by two further operations, corrected the eversion and deformity of the lower lip. Although these extensive operations were successful, nearly fifty years elapsed before a second bilateral resection to improve a

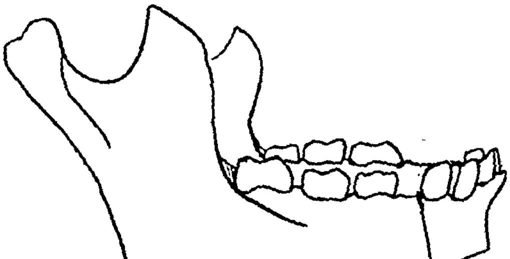

Fig. 2.—Diagram illustrating how the mobilized anterior segment was tilted back into occlusion in Hullihen's operation. This segment was held in position by a silver interdental splint. The nutrition of the separated portion of the jaw was maintained through its attachment to the lip. Similar types of operation are applicable to the upper jaw.

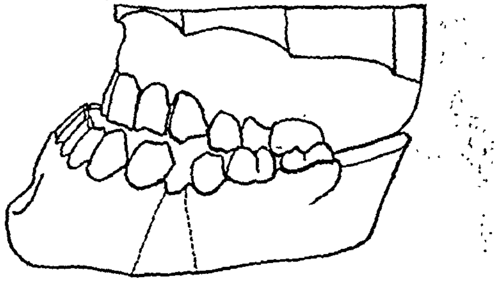

Fig. 3.—Diagram showing bilateral resection of the lower jaw advocated by Angle. A segment equal to that between the dotted lines is to be removed from each side of the jaw permitting the anterior part of the jaw to be brought into occlusion. The shape of the segments removed is to be modified by the conditions present in the particular case. Blair removed quadrilateral segments.

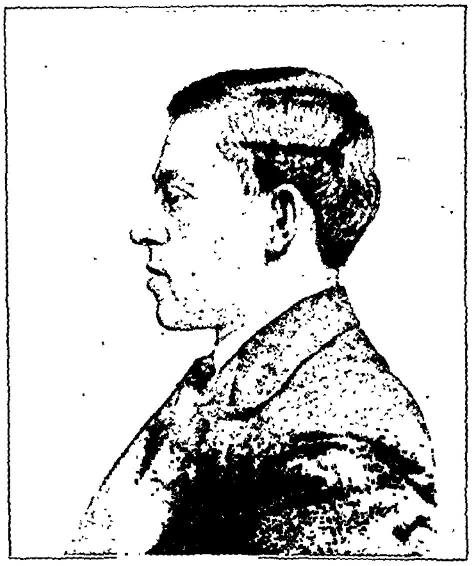

Fig. 4.—S. K., previous to operation, showing profile the result of inferior prognathism and malocclusion.

---

* Read in the Section on Stomatology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

[1] Hullihen, S. P.: Case of Elongation of the Jaw and Distortion of the Face and Neck Caused by a Burn Successfully Treated, Am. Jour. Dent. Sc., 1849, p. 157.

deformed jaw was undertaken. The patient, a young man with a progresssive type of prognathism, under the care of Dr. James W. Whipple, of St. Louis,[2] was referred to Dr. Edward H. Angle, who suggested a bilateral resection of the elongated portions of jaw between the first molar and second bicuspid on the right side and the first and second bicuspid on the left. A year later, in 1897, Dr. V. P. Blair performed this operation through angular incisions below the jaw. Despite imperfect retentive appliances, making it difficult to hold the fragments in proper position and the infection of the wounds, the patient, after nine very troublesome weeks, finally obtained bony union and marked improvement. Dr. Angle[3] in 1898 reviewed this operation and emphasized the importance of removing V-shaped or wedge-shaped sections of bone (Fig. 3) and of previously preparing from models accurate vulcanite or metal splints to hold the fragments in proper position. In these cases, Dr. Angle writes, "any orthodontic procedure is powerless to render improvement and the double resection becomes the only resort." The same operation was independently advocated in 1896 by Dr. R. Ottolengui,[4] to whom the idea was suggested, by observing a resection of the lower jaw for cancer. Since the time of Blair's operation double resection of the jaw has been performed but few times, and this apparently important subject has not been further developed by the orthodontist, while the surgeon, although interested in resections of the jaw for necrosis, tumor or ankylosis, apparently has not realized the field for surgical measures for deformities beyond the range of the usual orthodontic practice.

REPORT OF CASE

My attention was attracted to this subject by observing a patient whose history is as follows:

---

[2] Double Resection of the Inferior Maxilla for Protruding Lower Jaw, Dental Cosmos, 1898, p. 552.

[3] Double Resection of the Lower Maxilla, Dental Cosmos, 1898, p. 635; see also, Bellin: Items of Interest, June, 1908, p. 422; Blair: Items of Interest, November, 1908, p. 829.

[4] Discussion, Union Convention, Rochester, New York, Dental Cosmos, 1897, p. 143; Fowler: Items of Interest, January, 1897.

Patient.—Samuel K., aged 18, family history negative. No serious disease of childhood was recalled. During the past two winters he had had recurrent attacks of tonsillitis, but apart from this and a slight cold, he has had no illness for ten years.

Examination.—The tonsils were large; there was a moderate increase of adenoid tissue in the nasal pharynx; the nasal septum was inclined slightly to the right, and there was a chronic rhinitis of the hypertrophic type. The patient breathed almost exclusively through the mouth; the palate was highly arched, the dental arches were symmetrical and the teeth fairly regular, although small, short and poorly developed. Only the third molars on the left and the second and third on the right side could be occluded, the minimal separation between the upper and lower central incisors being 7 mm., and the lower centrals being in a plane at least 5 mm. in front of the upper centrals. The chin was rather pointed and prominent, and the patient said that, although the teeth were probably never in good occlusion, the condition had progressively increased during the past four years. The lips were long and the teeth did not show in ordinary conversation, so that the patient had been repeatedly asked if the teeth had been lost. In smiling and in talking the lips tended to curl in over the teeth, producing an unpleasant expression. In talking the tip of the tongue rested against the lower lip instead of the teeth so that enunciation had a mumbling character resembling that of an edentulous person. The patient could not bite hard or thin masses of food except by introducing them far into the mouth. Mastication was very imperfect, the food being bolted after a slight attempt at mastication. The lips were kept almost constantly open except during speech (Fig. 4). The patient was moderately well developed, but the chest was long and narrow. He was constipated but did not complain of indigestion.

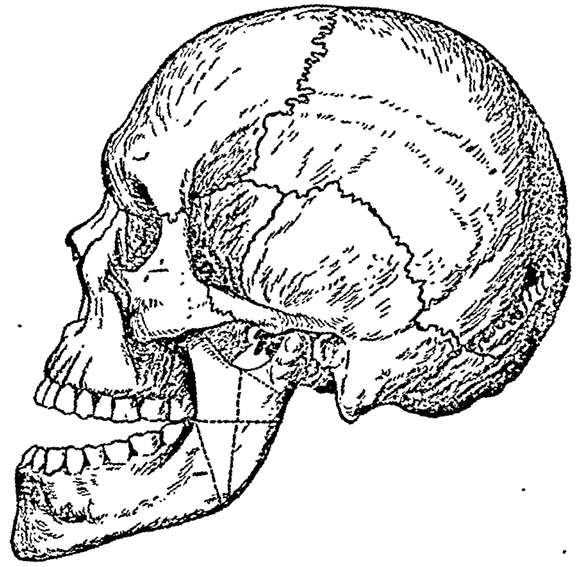

Fig. 9.—Diagram showing a condition of malocclusion, the dotted lines indicating various directions in which the ramus may be divided in order to overcome the deformity.

Choice of Measures of Relief.—The young man had presented himself for acne vulgaris, but the ugliness of the facial profile led me to examine the jaw and then to consider the possibility of surgical relief. At once it occurred to me that a section of both rami would be the operation of choice, but on investigation, to my surprise, I found no evidence that such an operation had ever been done previously. The patient was referred to Dr. S. H. Guilford to make sure that relief could not be obtained by any form of dental appliance. Dr. Guilford agreed as to the necessity for surgical intervention and suggested the operation of Angle. This operation seemed to me objectionable for the following reasons:

1. It would necessitate two compound fractures of the lower jaw.

2. At least one tooth with the adjacent process would have to be removed on each side, and in the removal of these two teeth the exposure of the roots of two adjacent teeth on each side of the mandible would be almost inevitable. Thus two teeth would be sacrificed, and four additional teeth placed in jeopardy.

3. The inferior dental canal with its vessels and nerves would be divided on each side.

4. The arch of the lower jaw would be broken into three portions, would be contracted and would require a special retentive appliance.

5. As the surface of bone would be exposed to the action of saliva and to infection in the mouth a greater or lesser degree of necrosis would be almost inevitable.

In one instance this operation was followed by loss of the mandible from necrosis.

The division of the inferior dental nerve seemed the least of these objections, as this nerve often reunites after division and even were the local anesthesia resulting from the division permanent the condition is not a very troublesome one. As contrasted with this operation a section through the ramus (1) would be free from dangers of a compound fracture within the mouth; (2) would not reduce the size of the dental arch or jeopardize any of the teeth; (3) if carried out above the level of the spine of Spix need not involve the inferior dental nerves or vessels; and (4), as the bone could be reached from without the mouth under aseptic precautions, the danger from aspiration would be slight even should suppuration or necrosis ensue. The septic fluids would be discharged externally and not pass into the mouth to be swallowed or be aspirated in the lungs; (5) the proper occlusion could be produced if necessary by external pressure through a chin-cup, if need were, without the use of any interdental appliance.

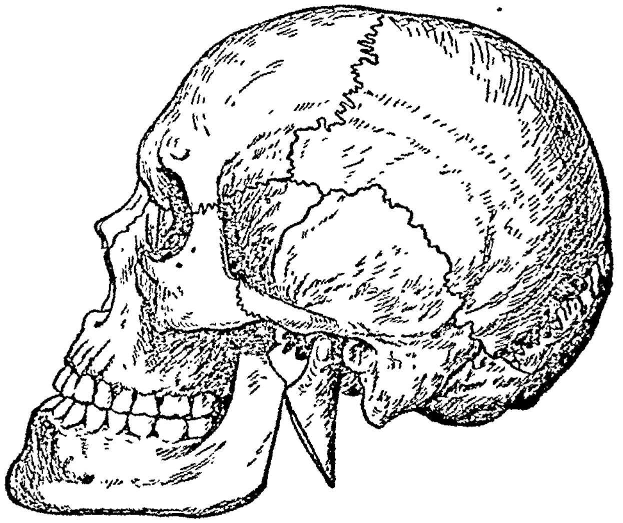

Fig. 10.—Result of a vertical division of the ramus. This line of section interferes with the leverage of the temporal muscle by approximating the coronoid and condyloid processes and tends to cause a marked posterior displacement of the lower part of the smaller fragment.

As an objection to a section of both rami, my attention was called to the narrow antero-posterior diameter of the pharynx, and the danger of producing suffocation by carrying the lower jaw and the attached tongue backward. As the support of the hyoid bone would not be changed by the operation, and as it seemed to be quite feasible to reproduce the deformity should signs of suffocation follow from the procedure, the following operation was undertaken:

Operation.—The patient was narcotized by scopolamin-morphin reinforced by a small amount of ether, Dec. 5, 1908, and an incision carried through the skin and subcutaneous tissue over the posterior border of the ramus of the jaw from the zygoma to a point under and anterior to the angle of the jaw. This incision was not carried through the deeper tissues for fear of injuring branches of the facial nerve and parotid duct. The outer fibers of the masseter muscle were separated and the external surface of the middle of the ramus exposed. With a small chisel a transverse section was then made through the deformed jaw was undertaken. The patient, a young man with a progresssive type of prognathism, under the care of Dr. James W. Whipple, of St. Louis,[2] was referred to Dr. Edward H. Angle, who suggested a bilateral resection of the elongated portions of jaw between the first molar and second bicuspid on the right side and the first and second bicuspid on the left. A year later, in 1897, Dr. V. P. Blair performed this operation through angular incisions below the jaw. Despite imperfect retentive appliances, making it difficult to hold the fragments in proper position and the infection of the wounds, the patient, after nine very troublesome weeks, finally obtained bony union and marked improvement. Dr. Angle[3] in 1898 reviewed this operation and emphasized the importance of removing V-shaped or wedge-shaped sections of bone (Fig. 3) and of previously preparing from models accurate vulcanite or metal splints to hold the fragments in proper position. In these cases, Dr. Angle writes, "any orthodontic procedure is powerless to render improvement and the double resection becomes the only resort." The same operation was independently advocated in 1896 by Dr. R. Ottolengui,[4] to whom the idea was suggested, by observing a resection of the lower jaw for cancer. Since the time of Blair's operation double resection of the jaw has been performed but few times, and this apparently important subject has not been further developed by the orthodontist, while the surgeon, although interested in resections of the jaw for necrosis, tumor or ankylosis, apparently has not realized the field for surgical measures for deformities beyond the range of the usual orthodontic practice.

REPORT OF CASE

My attention was attracted to this subject by observing a patient whose history is as follows:

---

[2] Double Resection of the Inferior Maxilla for Protruding Lower Jaw, Dental Cosmos, 1898, p. 552.

[3] Double Resection of the Lower Maxilla, Dental Cosmos, 1898, p. 635; see also, Bellin: Items of Interest, June, 1908, p. 422; Blair: Items of Interest, November, 1908, p. 829.

[4] Discussion, Union Convention, Rochester, New York, Dental Cosmos, 1897, p. 143; Fowler: Items of Interest, January, 1897.

Patient.—Samuel K., aged 18, family history negative. No serious disease of childhood was recalled. During the past two winters he had had recurrent attacks of tonsillitis, but apart from this and a slight cold, he has had no illness for ten years.

Examination.—The tonsils were large; there was a moderate increase of adenoid tissue in the nasal pharynx; the nasal septum was inclined slightly to the right, and there was a chronic rhinitis of the hypertrophic type. The patient breathed almost exclusively through the mouth; the palate was highly arched, the dental arches were symmetrical and the teeth fairly regular, although small, short and poorly developed. Only the third molars on the left and the second and third on the right side could be occluded, the minimal separation between the upper and lower central incisors being 7 mm., and the lower centrals being in a plane at least 5 mm. in front of the upper centrals. The chin was rather pointed and prominent, and the patient said that, although the teeth were probably never in good occlusion, the condition had progressively increased during the past four years. The lips were long and the teeth did not show in ordinary conversation, so that the patient had been repeatedly asked if the teeth had been lost. In smiling and in talking the lips tended to curl in over the teeth, producing an unpleasant expression. In talking the tip of the tongue rested against the lower lip instead of the teeth so that enunciation had a mumbling character resembling that of an edentulous person. The patient could not bite hard or thin masses of food except by introducing them far into the mouth. Mastication was very imperfect, the food being bolted after a slight attempt at mastication. The lips were kept almost constantly open except during speech (Fig. 4). The patient was moderately well developed, but the chest was long and narrow. He was constipated but did not complain of indigestion.

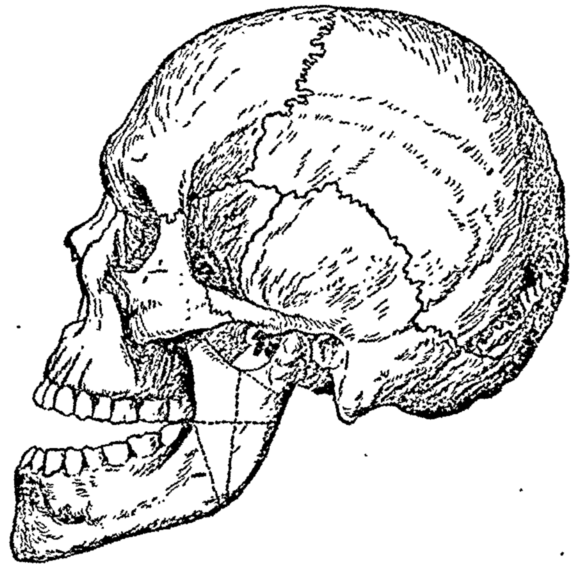

Fig. 9.—Diagram showing a condition of malocclusion, the dotted lines indicating various directions in which the ramus may be divided in order to overcome the deformity.

Choice of Measures of Relief.—The young man had presented himself for acne vulgaris, but the ugliness of the facial profile led me to examine the jaw and then to consider the possibility of surgical relief. At once it occurred to me that a section of both rami would be the operation of choice, but on investigation, to my surprise, I found no evidence that such an operation had ever been done previously. The patient was referred to Dr. S. H. Guilford to make sure that relief could not be obtained by any form of dental appliance. Dr. Guilford agreed as to the necessity for surgical intervention and suggested the operation of Angle. This operation seemed to me objectionable for the following reasons:

1. It would necessitate two compound fractures of the lower jaw.

2. At least one tooth with the adjacent process would have to be removed on each side, and in the removal of these two teeth the exposure of the roots of two adjacent teeth on each side of the mandible would be almost inevitable. Thus two teeth would be sacrificed, and four additional teeth placed in jeopardy.

3. The inferior dental canal with its vessels and nerves would be divided on each side.

4. The arch of the lower jaw would be broken into three portions, would be contracted and would require a special retentive appliance.

5. As the surface of bone would be exposed to the action of saliva and to infection in the mouth a greater or lesser degree of necrosis would be almost inevitable.

In one instance this operation was followed by loss of the mandible from necrosis.

The division of the inferior dental nerve seemed the least of these objections, as this nerve often reunites after division and even were the local anesthesia resulting from the division permanent the condition is not a very troublesome one. As contrasted with this operation a section through the ramus (1) would be free from dangers of a compound fracture within the mouth; (2) would not reduce the size of the dental arch or jeopardize any of the teeth; (3) if carried out above the level of the spine of Spix need not involve the inferior dental nerves or vessels; and (4), as the bone could be reached from without the mouth under aseptic precautions, the danger from aspiration would be slight even should suppuration or necrosis ensue. The septic fluids would be discharged externally and not pass into the mouth to be swallowed or be aspirated in the lungs; (5) the proper occlusion could be produced if necessary by external pressure through a chin-cup, if need were, without the use of any interdental appliance.

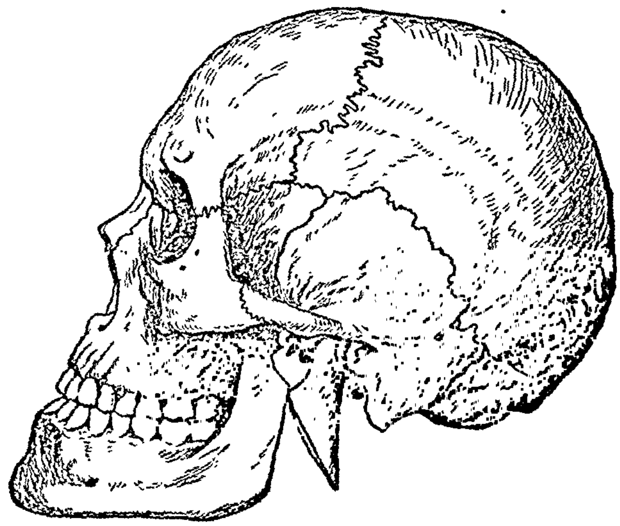

Fig. 10.—Result of a vertical division of the ramus. This line of section interferes with the leverage of the temporal muscle by approximating the coronoid and condyloid processes and tends to cause a marked posterior displacement of the lower part of the smaller fragment.

As an objection to a section of both rami, my attention was called to the narrow antero-posterior diameter of the pharynx, and the danger of producing suffocation by carrying the lower jaw and the attached tongue backward. As the support of the hyoid bone would not be changed by the operation, and as it seemed to be quite feasible to reproduce the deformity should signs of suffocation follow from the procedure, the following operation was undertaken:

Operation.—The patient was narcotized by scopolamin-morphin reinforced by a small amount of ether, Dec. 5, 1908, and an incision carried through the skin and subcutaneous tissue over the posterior border of the ramus of the jaw from the zygoma to a point under and anterior to the angle of the jaw. This incision was not carried through the deeper tissues for fear of injuring branches of the facial nerve and parotid duct. The outer fibers of the masseter muscle were separated and the external surface of the middle of the ramus exposed. With a small chisel a transverse section was then made through the ramus. The operation was repeated on the other side, and the body of the jaw then forced back, and the teeth placed in the best possible occlusion. To facilitate this a triangular segment of the ramus was removed on one side, a procedure probably unnecessary, and especially undesirable if the wedges, to be later described, had been used. The opening in the muscle, fascia and external wound was then carefully closed by buried sutures of catgut, certain of the lower teeth wired to the upper and an external plaster bandage applied. No symptoms of suffocation were produced, but on awaking the patient complained that there was insufficient room in his mouth for his tongue and that he had difficulty in breathing through his nose. The occlusion of the jaws closed the lips, and made them appear redundant.

Postoperative History.—In the after course of the case it was found that the contraction of the masseter muscles and the depressors of the jaw, by closing the triangular gap in the ramus, tended to separate the jaws anteriorly and the wiring of the teeth was found to be insufficient and was discarded. Through Dr. Guilford an interdental splint was constructed, but this likewise was not found of much advantage, so that recourse was had to pressure of an ordinary aluminum chin-cup connected by elastic bands to a head-piece. By regulating the tension of the bands it was found possible to bring the teeth into occlusion. This appliance was worn about nine weeks to give sufficient time for the new bony tissue to fill the gaps in the rami, but two weeks or more before the appliance was removed the patient began voluntarily to separate and to use the jaws. There was no tendency to ankylosis and the lateral and vertical movements of the jaw were well retained. As a result of the operation the patient's appearance has been greatly improved (Fig. 7), the lips have become shorter, the chin less prominent, the mouth is kept constantly closed, the enunciation of words is better, nasal respiration has been spontaneously established, food is properly masticated, the tongue is no longer kept between the teeth, the chronic constipation has disappeared, and, possibly as a result of the operation, or the cessation of mouth-breathing, there has been no attack of tonsillitis this winter, although the tonsils remain enlarged and the nasal catarrh continues.

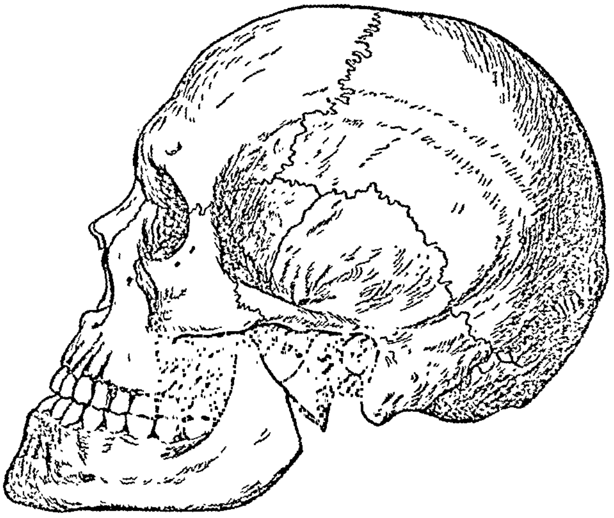

Fig. 11 Result of correcting the deformity by a section through the base of the condyloid process. This line of section reduces the leverage of the temporal muscle, and from lack of fixation of the smaller fragment would seem to involve a greater tendency to pseudarthrosis than certain other lines of section.

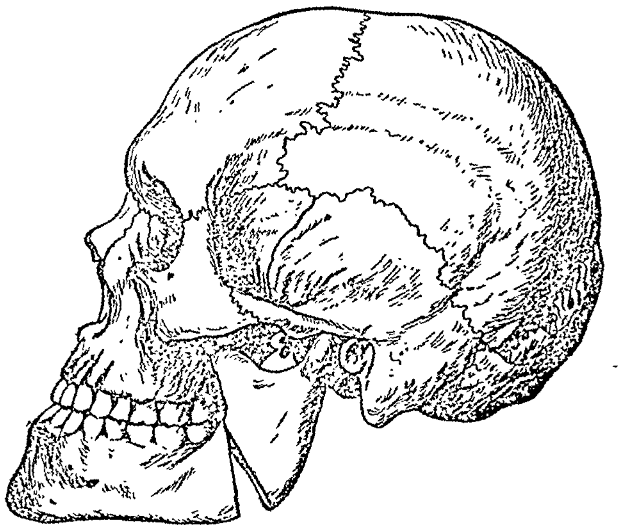

Fig. 12.—Results of a section between the ramus and the body of the jaw. The inferior dental canal is divided, the angle of the jaw increased, and the section is not so well adapted for the correction for prognathism. For lateral displacements of the jaw, this line of division, made on the side of the displacement may be useful.

For those who consider enlarged tonsils, adenoids and nasal obstruction a cause of mouth-breathing and of faulty development of the jaws, we have here some suggestive evidence that the correction of deformities of the jaw may conversely at times be followed by the spontaneous disappearance of the nasal obstruction and by failure of the large tonsils to produce symptoms. By this I would not controvert accepted theories, but would suggest the thought that mouth-breathing and oral deformities may at times be the primary and enlarged tonsils, adenoids and nasal obstructions secondary conditions.

METHOD OF DIVIDING THE RAMUS

In determining the best direction for the line of section to be made through the *ramus* in the above case a series of interesting observations shown in the accompanying diagrams were made (Fig. 9). By a vertical section through the ramus (Fig. 10) the lower portion of the posterior fragment is pushed far back, leaving a large V-shaped gap with the apex above. The angle of the jaw is, therefore, carried much farther back than normal, while the distance between the coronoid and condyloid process is much decreased, reducing the leverage of the temporal muscle. In those conditions in which the mandible is not undershot but in which it is merely desirable to approximate the anterior teeth such a line of section might be worthy of consideration.

A section through the base of the condyloid process, as shown in Figure 11, produces less deformity but also reduces the distance between the condyloid and coronoid processes. The small size of the posterior fragment and the lack of extensive muscular attachment might favor the production of a false joint after such an operation.

An oblique section running from above, downward and backward through the lower part of the ramus, as shown in Figure 12, leaves the bulk of the ramus intact and produces a moderate grade of deformity. A section of this type, or one more nearly vertical, could be employed for lateral deviations of the mandible, the line of section, of course, to be made on the side toward which the jaw deviated, as the separation of the fragments by a wedge would cause the jaw to be carried to the opposite direction correcting the deformity.

In Figure 13 is shown the result of correcting the deformity by a transverse section of the ramus on a line approximating the masticating surfaces of the teeth. As this line of section gave the least secondary deformity and as both fragments are well fixed by muscular attachments, this line was the line of section decided on in the present case. The strong masseter muscle splints the two sections and binds them firmly together. Indeed, the pull of the masseter muscle by tending to close the gap in the ramus so strongly tends to tilt the chin downward that a firm counter-support is necessary.

To obviate this we have now devised wedges of ivory or magnesium to be slipped between the separated portions of the ramus (Fig. 14), so as to put the posterior fibers of the masseter muscle on the stretch and to tilt the chin upward. In this way the chief difficulty in the after-treatment, the tendency of the chin to drop, is overcome. The wedges are very much the shape of an ordinary collar-button, the extended flange at each side tending to prevent displacement. To provide for the varying thickness of different rami I have had the wedge constructed like a small bolt, the thin flat head of the bolt being approximated to the inner surface of the ramus of the jaw, and an outer flat nut being screwed down, holding the parts firmly in apposition. Ivory and magnesium are the substances selected for the appliances, as each is susceptible to sterilization, and to absorption when buried in the tissues.

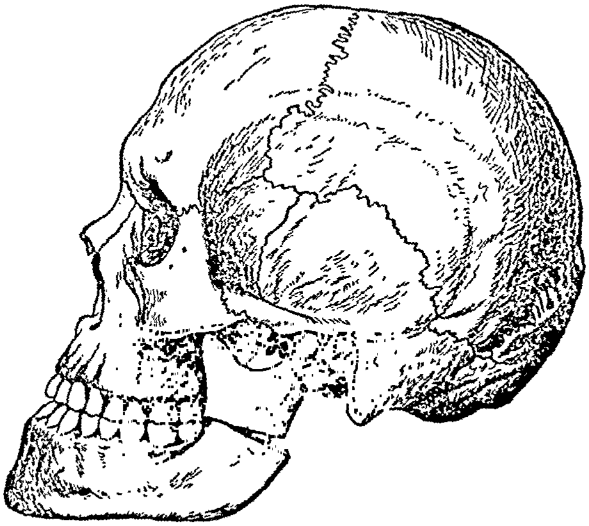

Fig. 13.—Transverse line of ramus division selected in the case of S. K. This line of section produces the least deformity, and if placed above the level of the *spine of Spix* enables one to avoid injury to the contents of the inferior dental canal and, moreover, does not interfere with the normal leverage of the temporal muscle. Both fragments have extensive muscular attachments serving to splint the parts after operation. The dotted line indicates the outer plate of the wedge of ivory or magnesium suggested by the author to maintain the elongation of the ramus, and to overcome the traction of the masseter muscle.

The section may be carried out by means of a small chisel, a burr actuated by a surgical engine, or the spiral osteotome of Cryer. The chisel has the advantage of the fact that it may be manipulated through a very small incision and with very little exposure of the bone. A vertical incision one inch long placed in front of the ear will enable one experienced in the use of the chisel to make the required section. Indeed, a narrow chisel may even be carried through the skin through a mere puncture and the bone division accomplished by the sense of touch alone. The section may likewise be carried out from the inside of the mouth with no external incision. The mouth is widely opened, a vertical incision made over the anterior border of the ramus through the mouth, as in Paravicini's operation, the tissues separated from the inner surface of the ramus, care being taken to avoid the internal lateral ligament, and, guided by the finger introduced through the incision, the bone divided by means of an appropriate burr or chisel.

There is some danger of necrosis of the ramus from infection from the mouth after such an operation. In a number of instances, however, in which I have exposed the inner surface of the ramus in this manner and have injected solutions of osmic acid into the inferior dental nerve, no troublesome necrosis has resulted despite the contact of the bone with saliva and an irritating chemical solution.

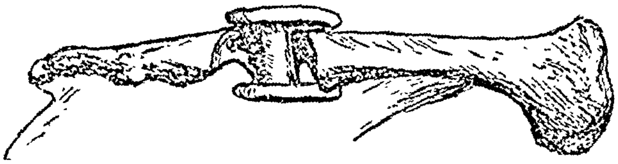

Fig. 14.—Wedge introduced into the line of section, viewed from behind. The introduction of this wedge overcomes the tendency of the anterior part of the jaw to tilt downward.

Besides necrosis a disadvantage in this method, however, is that an accurate approximation and support of the fragments by wedges can not be obtained and recourse must be had to interdental splints or the use of the chin-cup until the bone be united and the gap filled. Of course, in most instances, interdental splints firmly applied previous to the operation, to be later wired or bolted together, afford the best method of retention.

In considering the operative treatment of a deformity of the jaws one should not limit himself to the consideration of a single operation but should, until further advances have been made, consider the following possibilities:

1. By surgical measures it is possible (a) to change the relation between the body of the lower jaw and the rami so as to produce protrusion, recession, tilting or lateral displacement of the body of the jaw upon the ramus; (b) to change the shape of the arch of the jaw, either increasing or decreasing the size of the arch or altering its form; (c) to change the relative position of an anterior section of the jaw as related with a posterior section of the body and ramus; (d) to transplant and change the position of segments of the alveolus with contained teeth, the arch of the jaw not being completely divided, nutrition being maintained by the preservation of attachments to the soft tissues.

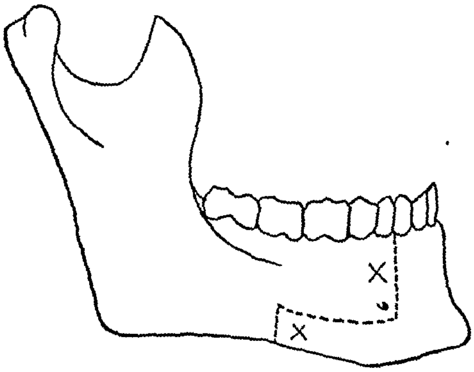

Fig. 15.—Diagram showing line of section suggested to enlarge the arch of the jaw. After the mandible has been divided as indicated by the dotted lines the segments are separated sufficiently to secure the proper occlusion and are maintained in position during the process of healing by an appropriate interdental splint or other appliance. By resecting the segments of bone indicated by XX the same line of section may be used to diminish the size of the arch of the jaw. By placing the incision anteriorly, the arch may be widened; by placing the line of section laterally one or both sides may be lengthened as desired.

2. When it is found by a study of models in the particular case that a correction of the deformity and a fair occlusion may be obtained without dividing the dental arch, the preferred operation is the section of one or

both rami along the lines found to be best adapted to the particular case. This operation is useful for many cases of prognathism, receding chin, and certain lateral deviations of the jaw. In certain instances, as in hypoplasia, it may be necessary to combine it with other operations designed to increase the size of the arch.

3. Where it is desired to enlarge the dental arch I would suggest the operation indicated in Figure 15. In this operation a vertical section of the alveolus is carried two-thirds of the way through the jaw, the line section is then carried at right angles for a variable distance and the remaining third of the jaw then divided parallel to but in a different plane from the first vertical section. The arch is then to be opened by sliding the segments of the jaw on each other and fixation in the proper position secured by adjusting an appropriate interdental splint or other appliance which previously has been prepared. By doing this operation on the anterior part of the jaw the arch may be widened, and if placed laterally one or both sides of the arch may be lengthened. With a resection of the divided bone ends, this operation may likewise be used to reduce the arch at any point, or the arch may be reduced by a simple resection of a V-shaped or wedge-shaped section of bone as may be found desirable.

4. To change the plane of occlusion of only a segment of the jaw, a bilateral V-shaped or wedge-shaped resection after the method of Angle may be used or an osteoplastic section after the plan of Hullihen.

5. Somewhat similar operations are to a lesser degree available for the deformities of the upper jaw. Kocher has shown that a transverse supra-alveolar resection on the superior maxilla is feasible, and as this operation may be used to mobilize one-half or the entire dental arch, it is obvious that it will enable decided changes in position for the correction of deformity. The separation of the superior maxilla in the mid-line or a plastic displacement of a portion of the alveolus with the contained teeth is likewise feasible. Unfortunately most of these operations are more difficult and attended with more serious hemorrhage and other complications than the operations on the lower jaw. The fixation of the mobilized portions of jaw after these operations, however, involves less difficulties than in the case of the mandible.

The above operations are briefly mentioned to indicate the surgical procedures which may be employed for the correction of deformities when the less serious orthodontic measures are unavailing and to stimulate the development of this field. A consideration of forms of malocclusion resulting from the diseases of the temporomaxillary articulation and malformation of the bone which interfere with the normal movements of the jaw is considered beyond the scope of the present paper.

2033 Walnut Street.

ABSTRACT OF DISCUSSION

Dr. J. E. Nyman, Chicago: I think that the successful operation reported presents a solution of the distressing conditions which are so frequently brought to our attention, and for which orthodontia can do little or nothing, and that is unilateral hypertrophy of the jaw between the shaft and the ramus. I have had three cases of unilateral hypertrophy in a practice of about fifteen years. Unfortunately I could suggest no operation which bade fair to produce favorable results. It seems to me that this operation will be of especial service in unilateral hypertrophy.

I think that frequently the fact that there is delayed union along the lines of section where a saw or burr has been used, is not so much because heat has been developed, but because of the fact that innumerable spicules of bone have been left which act as foreign bodies which must be absorbed or thrown off before regeneration and formation of new tissue can take place.

Dr. George V. I. Brown, Milwaukee: Dr. Babcock's paper is a beautiful exposition of his subject and of the method of his operation. The result is phenomenal. I did not believe such a result could be secured and have hitherto felt it safer to cut off the entire anterior portion of the jaw and have some dentist put in bridge work to complete the case, as was done in one of my cases in which the jaw extended so far forward as to make this possible. In another case the jaw was too short and we gave prominence to the chin, yet both resulted from burns.

I have looked with a good deal of skepticism on operations that have been described and recommended from time to time for patients requiring removal of sections of the jaw as described by Dr. Babcock, but his description is so complete and the result so perfect, that I see the promise of great good results in the future.

Dr. S. L. McCurdy, Pittsburg, Pa.: In a case similar to this which came to me a few months ago there was much separation of the incisors. The molars came together and there appeared to be a projection. I decided as the easiest and best operation to extract the lower molars and then chisel away the alveolar process as far as necessary, so that when the mouth was closed the incisors came in contact; the upper molars did not come in contact with the place where the lower molars had been extracted, and after that I removed two teeth, one on each side. Later the dentist made an appliance which increased the number of teeth which could be used for mastication, and the result was satisfactory; not, however, so satisfactory as that obtained by Dr. Babcock, and I think this will be the operation selected in the future.

Dr. A. R. Dray, Philadelphia: I feel indebted to Dr. Babcock for demonstrating his operation for the cure of a condition which hitherto has baffled the best efforts of the orthodontist and the dental surgeon. I did not exactly catch how Dr. Babcock immobilized the lower jaw while union was taking place. He referred briefly to an interdental splint, a poor thing at best. In case of ordinary fracture I think he would be tempted to discard appliances placed beneath the chin in order to prevent mobility. Wiring together the teeth of opposing jaws I have found is a splendid way to maintain a fixed position for fractures, and the operation described by Dr. Babcock is of course for a fracture of the inferior maxilla.

Dr. S. L. McCurdy, Pittsburg, Pa.: I should like to place myself on record at this time in connection with the question of repair of bones. I have been practicing the wiring of long bones by allowing them to remain *in situ*, recognizing the fact that when a bone was disturbed at the point of fracture or when we had an ununited fracture which required wiring, if during the process of freshening the ends of the bones or sawing them off they were torn and dragged about, and the soft tissues attached to the ends of these bones torn loose and the peritoneum stripped, we could not expect to have repair of the bone. I make this statement because I have seen a number of these operations performed, and the general surgeon usually does a through and through wiring which requires a great deal of destruction of soft tissues. The soft tissues must be preserved about the field of operation or nutrition will be destroyed and exfoliation will result in addition to the fact that there will be no union.

In a paper I read in Boston recently I described an operation of wiring which did not include a complete through and through drill, but a wiring of just half the bone. With the notched drill one can pull the wires through from the central canal.

Dr. W. Babcock, Philadelphia: The advantage of the chisel is that it enables one to work through a very small opening, does very little injury to the adjacent bone, and at the same time forms a very linear incision. The operation may be done in a very simple way, similar to an osteotomy of a long bone, by puncturing the soft tissues and carrying the chisel to the bone, the division of which occurs under the sense of touch. It is possible, therefore, to make this line of section with practically no external disfigurement, and with little injury to the adjacent tissues. The objection which is raised to the chisel when used on the skull, the concussion of the brain, hardly holds when one deals with the mandible, since this bone is fairly insulated from the skull proper.

Regarding the great field of purely orthodontic methods, I would again emphasize the fact that the oral surgeon in this field of work should be the associate and assistant of the orthodontist, and he must depend on those skilled in orthodontia to tell him when operation is necessary. In this case, I felt it was not proper for me to operate without putting this patient in the hands of my dental colleague to see if something could be done without operation. Moreover, after the operation has been done, as in this case, there often will remain some residual deformity to be corrected by appliances. The surgeon hews out the rough structure and leaves the finishing touches to be worked out later by the dentist.

In answer to the other questions, I would say that I first wired the teeth and depended on a plaster bandage, but the tension pulled the wires from the teeth. The degree of the pull during the first days is amazing. The condition is one in which the surgeon is really lengthening the ramus, and the attached muscles contract to prevent this lengthening. The result is that one has at the long end of the lever a traction which requires firm retention, preferably a full interdental splint. In this case, after wasting two or three weeks with plaster bandages and other appliances, I depended entirely on a chin cup with strong traction by rubber bands. In the interval the jaw had slipped slightly forward and the bone had partly filled in and something of the original correction was lost. This was left on in all about nine weeks. During the last three the patient began to chew food and use his jaws. It has been said that there is a danger theoretically of death with this type of operation. I think the mortality will be extremely small, as there is no danger from the inhalation of septic material, as when the mucosa is incised.

The oral surgeon is very fortunate in that he deals with bones especially well supplied with nourishment. He can do more than can the general surgeon—he can produce more mutilation and get better final results than perhaps can be obtained in any other part of the body. Those of you who have seen the crushes of the bones of the face, and have seen how the fragments unite after being placed in position will realize this. The perfect immobilization of bone fragments in the treatment of fractures seems to reduce the amount of callus formation. Too much callus, on the other hand, might give deformity. Although there was some play in this case, not enough callus was thrown out to be disfiguring. The bones of the head as a rule produce very little callus.

It makes little difference what else one uses so long as the teeth are kept properly together there is very little tendency for the fragments to slide one way or the other, as they are immobilized by the muscles.

INFANTILE ECZEMA *

ISAAC A. ABT, M.D.
CHICAGO

Infantile eczema occupies an important place in the clinic of children's diseases, and frequently presents great difficulties in its management. The etiology and pathology of this affection are as yet but little understood, and knowledge concerning them is needed. Even the most distinguished pathologists are not agreed as to the entire clinical history of this morbid process, whether by infantile eczema we mean a definite disease or merely a symptom of some unknown process. It is the purpose of this paper to discuss briefly some of the more recent views expressed on this matter, and to present the clinical history of the affection.

ETIOLOGY

At the outset attention must be directed to the confusion which might arise through considering this form of eczema with other skin eruptions produced by irritation, such as that caused by dirt, perspiration, etc. The most rational view, based on clinical observation, would be to consider eczema an external manifestation of some internal disorder. Careful observation of these cases confirms a first impression that the lesion on the skin may be compared with a barometric index which fluctuates with the prevalence of internal storms. The skin lesion may have exhibited a tendency to disappear or at least to abate somewhat, though concomitantly with an attack, moderate or severe, of indigestion, or because of some error or indiscretion in diet, the disease reappears and spreads with great activity. In a word, it may be stated that true eczemas in children are dependent on constitutional disturbances. The presence of bacteria in the secretions or on the denuded surface may be the result of a secondary infection and should not be considered as positive evidence that there exists between these germs and the disease a causal relationship. Some of the older authors may be quoted in corroboration of this belief.

Henke[1] thought that eczema was due to overfeeding, both in quantity and quality. Jorg[2] noted that these eczemas occurred more frequently in well-fed, fat babies, and thought that overfeeding played an important part. Similarly, Bohn[3] thought that the disease was due to overfeeding and constipation. The French authors lay great stress on hereditary influences as causes of the disease. Thus, Comby[4] thinks that arthritis, eczema, gout, obesity, asthma and various neuropathic states in the parent tend to cause eczema in the offspring. That this view is based on facts is corroborated by every observer's clinical experience. In very many of these cases it is found that the family history shows distinctly evidences of gouty and arthritic states and allied conditions.

L. F. Meyer thought that overfeeding, especially of such organic foodstuffs as casein and fat, gave rise to an excessive elimination of salts in children. Leighton,[5] on the other hand, is convinced that eczema is frequently of neurotic origin, even in those cases in which some external irritant is active. He recognizes two forms of eczema, (1) the idiopathic or ganglionic form, originating along the tract of the sympathetic nerves, and (2) the peripheral or traumatic form.

Variot[6] asserts that well-developed children, especially, and breast-fed, as well as artificially nourished children, are attacked by the disease.

Gaucher found an inhibition of metabolism in every case of eczema, with an increase in the nitrogen extractives and the chlorids and a diminution in uric-acid excretion. He regards eczema as an autointoxication, the poisons being eliminated through the skin, and these poisons being the result of incomplete oxidation of the nitrogenous products.

Marfan[7] classifies these cases in two forms: The first form is characterized by the localization of the eczema on the scalp, the eruption being moist and crusty. Associated with the scalp eruption is a wet or crusty eruption on the cheeks and ears, the rest of the

face usually remaining free. This has been called milk-scab. Later in the course of the disease the eruption may spread to the hands and forearms, although, as a rule, the trunk and extremities are not affected. If the condition remains untreated or does not yield to treatment, the body, neck, arms and legs may be covered with a weeping, crusty eczema, while an intertriginous eruption covers the genitocrural folds. Dry fatty scales are usually found on the surface. Itching, as a rule, does not occur. This variety usually occurs in babies who have been fed artificially with large quantities of milk, eggs and meat broths. This form of the disease is most often of the seborrheic type, and, while the treatment is difficult, spontaneous recovery may occur at the end of the first year, when the quantity of milk is reduced.

The second form is described by Marfan under the name of disseminated, dry eczema. It occurs most frequently in artificially fed babies, and the history obtained is usually that of an overfed infant, who is thin and delicate, and who is suffering from chronic intestinal and nutritive disturbances, manifested by diarrhea, alternating with constipation, abdominal distention and loss of weight. The appearance of the skin is even worse than in the first form. There are dry, scaly, infiltrated islands of crusts with papular and pustular lesions, and sometimes moist areas. The face is usually most involved, the scalp only slightly. The eruption progresses slowly. The itching is very refractory to treatment. It has been suggested that this is the gouty form.

In some cases the first and second types merge into each other so much that no fixed or definite line can be drawn between the two varieties.

Among the complications of infantile eczema may be mentioned albuminuria, with or without kidney disease and heart involvement. Re[8] found albuminuria in twelve out of twenty-one cases, but these patients were also suffering from enteritis. The albuminuria and the heart complications are undoubtedly due to absorption of poisonous products, and many writers have
urged the necessity of paying more attention the
heart and kidneys of children suffering from

TREATMENT

The treatment of this condition resolves itself into local and constitutional measures, mainly the latter. The dermatologists who direct local treatment advise, in addition to the dietetic treatment, that the crusts be removed by softening with liquid petrolatum. In the eczemas of the scalp the removal must be gradual to prevent fever and other serious results. The aluminium acetate used as a poultice in most eczemas acts well in the removal of the crust. After the crusts have been removed the use of the following paste is advised, this being covered with a well-fitting mask:

℞	gm. or c.c.		
Zinci oxidi	27		ʒvii
Adipis lanæ hydrosi	4	or	ʒi
Liquoris calcis	30		fl.℥i
Olei amygdalæ expressi	4		fl.ʒi

M. et Sig.: Apply as directed.

In the milder cases a powder of zinc oxid, 30 per cent., and talcum, 70 per cent., acts well. Scratching is prevented by putting the arms in light splints. In the obstinate cases in which these measures do not seem sufficient, ointments of naphthalene (5 to 10 per cent.) for the itching, or sulphur (2 to 5 per cent.) in the seborrheic form, or salicylic acid (0.5 to 2 per cent.) in the dry disseminated type, may be employed.

When the moisture is no longer present, zinc oxid and olive-oil, equal parts of each, is often indicated. In the stubborn dry cases some tar ointment is often of service, as 0.1 to 1 per cent. oleum rusci or oleum cadini or a weakened tar oil, as unguentum picis of the National Formulary.

I have frequently found that the dry form yields to the application of simple cerate, which is dusted over with talcum or rice powder. Sulphur baths are sometimes u d and a short course of treatment with Fow-
ler's s n in the refractory cases and wine of col-
chicum e gouty cases yields good results. Where

8. Re; Pediatria, September, 1

On the whole, it may be said that a milk-poor, restricted diet with addition of cereal, the exclusion of eggs and meat broths, as a rule, yields good results in a short period of time. Older infants should also be given fruits and vegetables.

Langstein reports a case in which the Finklestein treatment failed absolutely. The patient finally recovered after the internal administration of large quantities of salt. Czerny emphasizes the necessity of treating any underlying hereditary factor which may have been operative in the production of the disease. The administration of thyroid extract has done well in some cases.

ABSTRACT OF DISCUSSION

Dr. D. E. English, Summit, N. J.: In making ointments I use unhydrated lanolin and soften it with lard oil, and in that way use only the animal fats.

THE SERUM TREATMENT OF EPIDEMIC MENINGITIS *

FRANK SPOONER CHURCHILL, M.D.
Assistant Professor of Pediatrics, Rush Medical College
CHICAGO

The bacteriology of meningitis is most varied and the cases may be divided into two groups, the tuberculous and the non-tuberculous. The tuberculous cases are due to invasion of the meninges by the bacillus of tuberculosis, the non-tuberculous to invasion by a great variety of organisms. The great majority of the latter group consist of those cases due to the *Diplococcus intracellularis* of Weichselbaum, 80 per cent. of non-tuberculous cases being due to this organism. It is familiarly known as epidemic meningitis. For the treatment of this particular form of meningitis we have now had for about two years a specific serum evolved by Simon Flexner. It is with this type of meningitis, and this alone, that this paper deals. It is with this type of meningitis, and this alone, that the Flexner serum is effective. It is useless in all other forms. This statement seems necessary in view of the requests which have been made of me to use the serum in tuberculous meningitis, in non-tuberculous meningitis due to the pneumococcus, to the streptococcus, in head injuries, and in meningitis occurring in the course of the various infectious diseases and secondary to intestinal infections. The specific nature of the serum must be borne disinctly in mind. It will do no more good in a pneumococcic or streptococcic meningitis than will diphtheria antitoxin in a pneumococcic or streptococcic tonsillitis.

The development of the serum is interesting. Flexner, studying the New York epidemic of meningitis in 1894, sought to influence favorably the course of the disease produced experimentally in animals by antiserums prepared in several kinds of animals from *Diplococcus intracellularis.* His first reports showed that the course of the disease in guinea-pigs and monkeys could be modified favorably and animals saved from the fatal effects of the diplococcus.

Subsequently Flexner and Jobling developed a diplococcus antiserum, prepared from the horse, which has now been used for about two years in the treatment of epidemic meningitis in man. They have collected up to date reports of about 600 cases, and the results in these cases justify the opinion expressed by them in an earlier publication: "It is our belief that the analyses of histories of cases of epidemic meningitis which have been presented furnish convincing proof that the antimeningitic serum, when used by the subdural method of injection in suitable doses and at proper intervals, is capable of reducing the period of illness; of preventing, in a large measure, the chronic lesions and types of the infection; of bringing about complete restoration to health in all but a small number of cases, the recovered, thus lessening the serious, deforming and permanent consequences of meningitis, and of greatly diminishing the fatalities of the disease." Their cases, taken as a whole, show a mortality of 25 per cent; in a few serious cases, in which treatment was begun within the first three or four days, the mortality was 11 per cent. Furthermore, among the 75 per cent. of recoveries, there were few of the serious sequelæ generally noticed after this infection. Hitherto the mortality in epidemic meningitis has ranged from 75 per cent. to 80 per cent., and among the patients who survived the persistence of serious sequelæ has been so great that their survival has been considered unfortunate. In other words, treatment of this infection by the Flexner serum has reversed the proportion of deaths and recoveries.

I have had the opportunity of watching the effect of the serum in 41 cases of meningitis, 29 of which have been proved to be of the meningococcic type. In these 29 proved cases, 16 patients have recovered and 13 have died, a mortality of 44 per cent. Closer analysis of the series shows that of 16 patients receiving the serum within the first week, 6, or 37 per cent., died. Of these 6 cases, 3 were fulminating and the patients died within the first two days; the fourth was a bartender aged 43 and the other 2 were not closely followed up, but each received only one dose of the serum.

This series of cases represents only one of many series, reports from all of which are sent to Flexner, for analysis by him, from time to time. His figures therefore are a better average test of the serum than are my smaller ones. It will be noted that the average mortality in my series is much higher than in the grand total of all series. I attribute this higher mortality in my series to the fact that many of the patients were treated in their own homes, at widely separated points in three different states; hence the difficulty of following them closely and giving repeated doses of the serum. On the other hand, those patients treated directly under the eye, in hospital, as a rule have done better than those treated at home. It is the latter group which have raised the mortality rate. I have therefore come to the conclusion that it is extremely desirable to send meningitis patients to the hospital; they can be watched more closely, the serum can be given more persistently and thoroughly; furthermore, more exhaustive and extensive laboratory investigations, as to blood, spinal fluid, etc., can be carried out in hospitals; the advisability of these investigations is especially great in these early days of the serum, when more accurate knowledge as to its exact action is desired.

Cases studied in detail show several interesting phenomena which have to do with the mortality rate, the method of termination, the general course of the disease and the effect of the serum on the spinal fluid.

The most striking thing, of course, is the high percentage of perfect recoveries, i. e., recoveries without serious sequelæ, and an especially low rate of mortality face usually remaining free. This has been called milk-scab. Later in the course of the disease the eruption may spread to the hands and forearms, although, as a rule, the trunk and extremities are not affected. If the condition remains untreated or does not yield to treatment, the body, neck, arms and legs may be covered with a weeping, crusty eczema, while an intertriginous eruption covers the genitocrural folds. Dry fatty scales are usually found on the surface. Itching, as a rule, does not occur. This variety usually occurs in babies who have been fed artificially with large quantities of milk, eggs and meat broths. This form of the disease is most often of the seborrheic type, and, while the treatment is difficult, spontaneous recovery may occur at the end of the first year, when the quantity of milk is reduced.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

The second form is described by Marfan under the name of disseminated, dry eczema. It occurs most frequently in artificially fed babies, and the history obtained is usually that of an overfed infant, who is thin and delicate, and who is suffering from chronic intestinal and nutritive disturbances, manifested by diarrhea, alternating with constipation, abdominal distention and loss of weight. The appearance of the skin is even worse than in the first form. There are dry, scaly, infiltrated islands of crusts with papular and pustular lesions, and sometimes moist areas. The face is usually most involved, the scalp only slightly. The eruption progresses slowly. The itching is very refractory to treatment. It has been suggested that this is the gouty form.

In some cases the first and second types merge into each other so much that no fixed or definite line can be drawn between the two varieties.

Among the complications of infantile eczema may be mentioned albuminuria, with or without kidney disease and heart involvement. Re[8] found albuminuria in twelve out of twenty-one cases, but these patients were also suffering from enteritis. The albuminuria and the heart complications are undoubtedly due to absorption of poisonous products, and many writers have urged the necessity of paying more attention to the heart and kidneys of children suffering from eczema. These children may also show symptoms of heart weakness or even collapse without fatal issue. In one case in which a postmortem examination was made, a very large thymus was present with a distinctly degenerated myocardium.

The clinical course of the disease rarely shows any sign of impending death, and a postmortem examination often fails to reveal the cause of death. There are those who believe that the status lymphaticus may explain this condition, though others oppose this view. The opinion has been expressed that sudden death may be due to a myocardial degeneration.

Castenholz attributed death to interference with cutaneous respiration. Others hold that death is caused by infection. Strauss maintains that eczema has nothing to do with the death, and that the infant dies from some other cause than the skin eruption. Heubner and Feer found in their autopsies on babies having eczema all the signs described by Paltauf as characteristic of the status lymphaticus.

As regards the etiologic relationship existing between eczema and asthma, several striking instances in confirmation of such a view have been noted.

TREATMENT

The treatment of this condition resolves itself into local and constitutional measures, mainly the latter. The dermatologists who direct local treatment advise, in addition to the dietetic treatment, that the crusts be removed by softening with liquid petrolatum. In the eczemas of the scalp the removal must be gradual to prevent fever and other serious results. The aluminium acetate used as a poultice in most eczemas acts well in the removal of the crust. After the crusts have been removed the use of the following paste is advised, this being covered with a well-fitting mask:

℞	gm. or c.c.		
Zinci oxidi	27		ʒvii
Adipis lanæ hydrosi	4	or	ʒi
Liquoris calcis	30		fl.℥i
Olei amygdalæ expressi	4		fl.ʒi

M. et Sig.: Apply as directed.

In the milder cases a powder of zinc oxid, 30 per cent., and talcum, 70 per cent., acts well. Scratching is prevented by putting the arms in light splints. In the obstinate cases in which these measures do not seem sufficient, ointments of naphthalene (5 to 10 per cent.) for the itching, or sulphur (2 to 5 per cent.) in the seborrheic form, or salicylic acid (0.5 to 2 per cent.) in the dry disseminated type, may be employed.

When the moisture is no longer present, zinc oxid and olive-oil, equal parts of each, is often indicated. In the stubborn dry cases some tar ointment is often of service, as 0.1 to 1 per cent. oleum rusci or oleum cadini or a weakened tar oil, as unguentum picis of the National Formulary.

I have frequently found that the dry form yields to the application of simple cerate, which is dusted over with talcum or rice powder. Sulphur baths are sometimes useful and a short course of treatment with Fowler's solution in the refractory cases and wine of colchicum in the gouty cases yields good results. Where constipation is a marked feature of the case I have frequently found laxative waters of value; in other cases, especially those of older children, the compound infusion of senna has relieved the constitutional symptoms and diminished the local irritation.

The constitutional treatment consists in the main in the regulation of the diet, although measures looking toward relieving any intestinal disturbances must not be overlooked nor underestimated. Dietetic treatment is usually sufficient to cure a beginning eczema and to prevent the occurrence of complications. Some clinicians restrict the amount of nourishment given, besides modifying its composition. The fact that the disease occurs in infants who are breast-fed as well as in those who are fed artificially, emphasizes the necessity of specific treatment of individual cases. Good results have been reported from the employment of what has come to be known as Finklestein's soup. Finklestein thought that this form of eczema was due to milk salts, regardless of fat or protein. Therefore, he coagulated the milk with pegnin, added one-fifth of the whey to the coagulum, and oatmeal water to make the original quantity. Cane sugar was added in varying quantites. A number of clinicians have employed the method, some with good success, while others met only failure. My personal experience has not been such as to warrant me to recommend this treatment.

Good results have also been obtained from the use of skimmed milk, buttermilk, gruel and predigested milk. Whey has yielded remarkably good results in some cases.

Of these 6 cases, 3 were fulminating and the patients died within the first two days; the fourth was a bartender aged 43 and the other 2 were not closely followed up, but each received only one dose of the serum.

This series of cases represents only one of many series, reports from all of which are sent to Flexner, for analysis by him, from time to time. His figures therefore are a better average test of the serum than are my smaller ones. It will be noted that the average mortality in my series is much higher than in the grand total of all series. I attribute this higher mortality in my series to the fact that many of the patients were treated in their own homes, at widely separated points in three different states; hence the difficulty of following them closely and giving repeated doses of the serum. On the other hand, those patients treated directly under the eye, in hospital, as a rule have done better than those treated at home. It is the latter group which have raised the mortality rate. I have therefore come to the conclusion that it is extremely desirable to send meningitis patients to the hospital; they can be watched more closely, the serum can be given more persistently and thoroughly; furthermore, more exhaustive and extensive laboratory investigations, as to blood, spinal fluid, etc., can be carried out in hospitals; the advisability of these investigations is especially great in these early days of the serum, when more accurate knowledge as to its exact action is desired.

Cases studied in detail show several interesting phenomena which have to do with the mortality rate, the method of termination, the general course of the disease and the effect of the serum on the spinal fluid.

The most striking thing, of course, is the high percentage of perfect recoveries, i. e., recoveries without serious sequelæ, and an especially low rate of mortality among those patients treated early in the disease, this mortality rate being as low as 10 per cent. in some series of patients treated within the first three or four days. Then the abrupt termination of the disease by crisis, in certain cases, has been most striking. Thus in 273 cases of recovery, Flexner and Jobling report 25 per cent. as terminating in this way.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

EFFECT ON THE COURSE OF THE DISEASE

The course of the disease is materially shortened by the serum and a turn for the better is often noticed soon after the first injection; the mentality is clearer, there is less headache and general pain, the temperature is lower and the general condition of the patient seems improved. The rigidities, however, are apt to persist, e. g., the stiffness of the neck, Kernig's sign, etc. It is a remarkable sight to see in the children's ward, for instance, a patient twelve to eighteen hours after an injection, lying with head thrown back, perfectly comfortable and rational, or perhaps even playing with his toys—the same patient who previous to his injection was tossing about in delirium, with headache, high temperature and all the signs of a severe infection.

EFFECT ON THE SPINAL FLUID

[illegible] effect of the serum on the spinal fluid is most interesting and is perhaps more demonstrable in this direction than in any other. The first puncture usually shows a fluid turbid in varying degree; smears from this fluid stained by the Gram method show a variable number of leucocytes, chiefly of the polymorphonuclear variety, and numerous Gram-negative diplococci, some intracellular, but more extracellular. Cultures on different media show an active growth, examination of which confirms the observation of the smears, i. e., a Gram-negative diplococcus. The first injection of serum is now given. Eighteen or twenty-four hours later the second puncture shows a fluid still turbid, more or less so than the first according to the progress of the case and *pari passu* an increased or diminished number of leucocytes, still of the polymorphonuclear variety. But bacteriologically we already see a change: there are more of the diplococci within the cells and fewer without than there were at the first puncture, i. e., phagocytosis has been going on to a considerable extent; at this time the number of cocci extracellular may exceed those intracellular, but with the progress of the case, whether favorable or unfavorable, the extracellular organisms gradually disappear entirely, the number within the cells at first increasing and later diminishing until they too disappear. The more rapid the progress of the case toward recovery, the more rapid the phagocytosis and the total disappearance of the organisms from the spinal fluid. The more protracted the case, the more persistent are the organisms; especially is this so in cases coming late under treatment.

The cultural character of the organisms changes with the progress of the disease; at first profuse, abundant growths are noticed on the media; gradually, however, they grow more slowly, less abundantly, less characteristically, and finally cease to grow. After they cease to grow on cultures, however, they may still be detected in smears; they are present, but apparently dying and too weak to take root and grow; in a short time they disappear from the smears also, of course.

THE CELLULAR ELEMENTS

The behavior of the cellular elements of the spinal fluid is also interesting. At the first puncture the leucocytes are numerous, remarkably so in some cases, and invariably of the [illegible] type, 90 to 95 per cent. usually. [illegible] s favorably the total number diminishes; they lose their characteristic morphology and staining qualities; the proportion of mononuclears is very apt to increase; indeed, in a few long-drawn-out cases the mononuclears have formed a large percentage of the cells.

TECHNIC

The method of giving the serum is important and I now describe it in detail.

All the active workers with the Flexner serum are of the opinion that, in order to get the best results, the serum must be brought closely in contact with the pathologic seat of the disease and that this can be done only by a lumbar puncture. It is useless to give it subcutaneously. After study of my own cases and those of other observers I have come to the following conclusions as to the method of using the serum:

In all cases which clinically resemble meningitis we must do a lumbar puncture; for this purpose we may use the needle of either a large antitoxin syringe or of a large aspirator, holding at least 30 c.c., the minimum dose to be given. Both patient and apparatus, of course, are to be surgically clean. The serum should be ready for injection. The puncture is to be made according to the usual rules laid down in text-books, i. e., in the third or fourth lumbar space, close to the spine, this point being determined by the imaginary line running from crest to crest of the ilia. The needle once in the spinal canal, the fluid begins to flow out; rarely is there any obstruction from clogging of the needle; if so it should be cleared with the obturator. The pressure of the fluid should be noted if possible with the sphygmomanometer or roughly by counting the number of drops per minute; its turbidity and color should also be noted

Collect a few drops of the fluid on clean glass slides for immediate staining and microscopic examination. Also inoculate several test-tubes of culture media by allowing the fluid to trickle directly over the media; finally collect the remaining fluid in a sterile test-tube for counting the contained leucocytes and centrifuging for further examination. Evacuate in all 30 to 45 c.c., if possible. If it be the least bit cloudy or turbid inject the serum at once, without waiting to learn the result of even the smears, injecting as follows: To the needle still in the spinal canal attach the syringe previously filled with the serum (warmed to about the body temperature). Inject slowly, using only gentle pressure in forcing down the piston, give 30 to 45 c.c., except in small babies in whom a smaller amount may be used. Thirty c.c. may be given even if the amount of spinal fluid removed is less than this. It is desirable, though not necessary, to remove spinal fluid equal in amount to the serum to be given.

EXAMINATION OF THE SPINAL FLUID

The spinal fluid should be examined immediately. The glass smears are stained by the Gram method and examined for both cellular elements and organisms; care should be taken to note the relative number of diplococci within and without the leucocytes. Fortunately the smears are fully as reliable as the cultures; hence we do not have to wait long for an exact diagnosis. The cultures should, of course, be incubated and examined later. The total number of leucocytes in the spinal fluid should be counted by the Thoma-Zeiss apparatus as soon after evacuation as possible.

REPETITION OF THE SERUM

If the bacteriologic examination show the presence of the diplococcus subsequent injections of the serum should be given. In the earlier days of the serum it was customary to wait, if improvement followed the first injection, until unfavorable symptoms developed, e. g., increased temperature, great restlessness, pain, headache, etc., and then give the second dose. Subsequent observations, however, especially by Dunn, have shown that better results are attained by giving the serum daily for three or four successive days, regardless of the clinical and bacteriologic progress of the case. The serum can do no harm, and this concentrated method of giving it is undoubtedly better than waiting for symptoms to arise and then hitting them. In severe and fulminating cases the second dose should be given in from twelve to eighteen hours after the first, and 45 c.c. should be given. In several instances I have used this amount of serum without bad results, even though less than this amount of fluid had been removed.

Having thus given our first series of three or four doses on successive days, we may pause and note results; as a rule, improvement will be seen both clinically and bacteriologically, and no further injections will be necessary, at least in patients coming early under treatment. But if after an interval of a day or two untoward symptoms still persist another series of doses should be given daily, perhaps for two days, perhaps for four days, then another pause be observed. This process of alternate giving and withholding of injections may be continued until meningeal symptoms have ceased or bacteria have entirely disappeared from the spinal fluid, or the chronic stage has been established. As a rule, it will be found that the diplococci disappear comparatively early, and that we may then cease our injections. If the serum is to be effective it will be so early in the disease after a few doses. If, however, the organisms persist in the spinal fluid for a long time occasional doses should be given. In all cases, whether those of complete recovery or those running on into the chronic stage, lumbar puncture should be done from time to time until no organisms are found either in smears or cultures. We must leave our patient with a sterile spinal fluid.

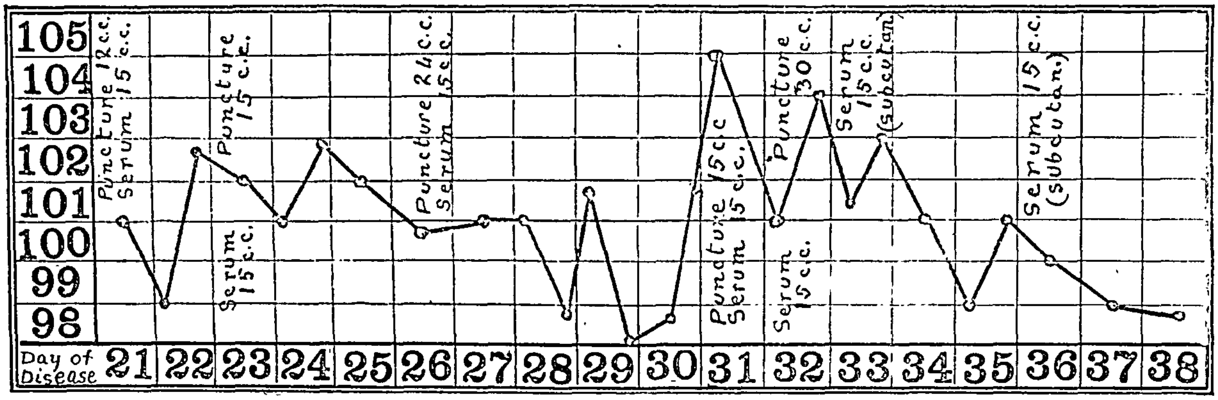

Chart 1.—Temperature curve in Case 1.

Relapses should be treated as fresh cases. Certain complications, if due directly to the meningococcus, may be an indication for the local use of the serum. Thus in one of my series a severe arthritis of the knee, proved by bacteriologic examination of the aspirated fluid to be due to the meningococcus, received three doses of 15 c.c. each, given directly into the joint, with immediate relief to the pain and apparent permanent improvement. Cushing has reported a similar case.

The following brief histories illustrate some of the points mentioned in this paper.

CASE 1.—This illustrates the disadvantage of coming late under treatment and the futility of giving small doses, scattered and in part subcutaneously. The patient, a nine-year-old boy, left the hospital apparently well, on the thirty-eighth day, but returned in three weeks with meningeal symptoms, from which he finally died five weeks later, the spinal fluid during this second stay in the hospital being sterile.

Chart 1 shows the temperature curve and method of dosage. It is a good illustration of how *not* to give the serum.

CASE 2.—George D., aged 3, entered my service at Cook County Hospital, April 13, 1909, on the fifth day of illness. He was given 30 c.c. of serum on each of the two following days, then through a mistake, none on the next two days, with consequent increase of symptoms, was then given 30 c.c. on each of the following four days, the last on the thirteenth day of the disease, with satisfactory results. The spinal fluid was sterile at the last puncture. The case illustrates the danger of ceasing injections too early and the value of sufficiently prolonged daily doses.

CASE 3.—A seven-year-old girl received her first injection on the second day. The case terminated by crisis after only two doses of the serum. Chart 3 tells the story graphically.

CASE 4.—In the case of Nately C., aged 15, the serum was not used persistently enough, and consequently we see a long-drawn-out case, though the patient finally recovered after individual, isolated doses at long intervals. The serum was given on the ninth, tenth, fourteenth, seventeenth, twenty-fourth, twenty-sixth and thirty-sixth days, respectively, the spinal fluid on the last date being sterile. The case also illustrates the value of perseverance in the use of the serum, even late into the disease. The patient was discharged from the hospital on the forty-third day.

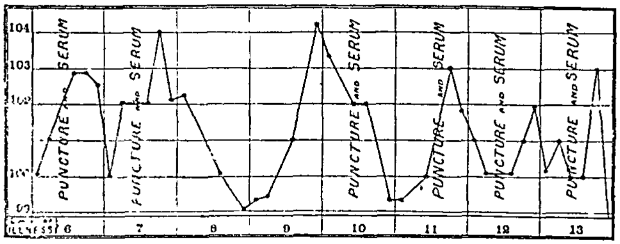

Chart 2.—Temperature curve in Case 2.

CASE 5.—This case, from the service of Drs. Poorman and Ellis Kerr, at the Oak Park Hospital, was a severe fulminating case. The patient, Amelia D., was given her first injection twenty-three hours after the onset, with marked improvement in the general condition, temperature and spinal fluid. The injection was repeated on the second day, omitted on the third with increase in symptoms, given on the fourth and fifth days.

with diminution of the meningeal symptoms, but continued high temperature due to arthritis of the right knee joint. Fluid aspirated from this joint showed the meningococcus; serum, 15 c.c., was therefore injected directly into the joint on the ninth, tenth and eleventh days respectively, with much relief to the pain. Serum, 30 c.c., was also injected into the spinal canal on the seventh and ninth days, respectively, the fluid from the last puncture being sterile. A further complication, apparently an osteomyelitis of the right femur, prolonged the convalescence, but this also eventually disappeared and the patient has now, June 9, had a normal temperature for two weeks and is steadily improving.

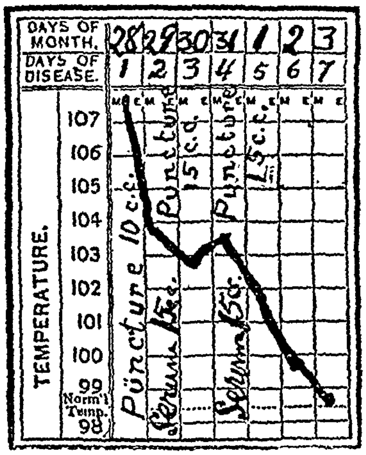

Chart 3.—Temperature curve in Case 3.

The actual disease itself, the meningitis, in this case, was evidently checked by the first two doses of the serum, as was demonstrated, not only by the diminution in the meningeal symptoms, but also by improvement in the character of the spinal fluid. The termination of the disease itself was by crisis; indeed, it might almost be said that it aborted, so sudden and remarkable was the drop in the temperature. The prolonged character of the case was due to the complications, over which the serum had no apparent control, aside from the relief of joint pain when locally applied.

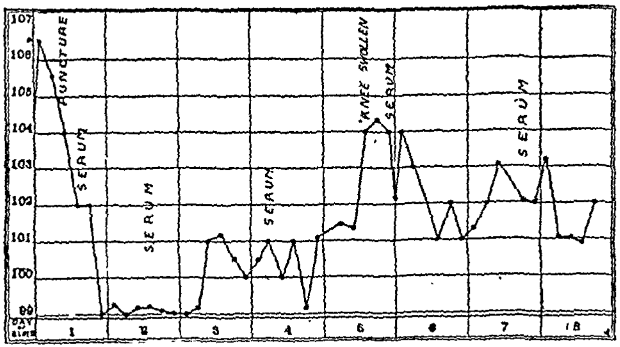

Chart 4.—Temperature curve in Case 5.

SUMMARY

The main points in this paper may be briefly summarized as follows:

1. In all cases clinically suggesting meningitis, do a lumbar puncture as early as possible.

2. If the fluid thus obtained be turbid, immediately inject at least 30 c.c. of Flexner serum directly into the spinal canal without waiting to hear the bacteriologic report of the fluid.

3. Examine the spinal fluid [illegible] are more important than cult[illegible] *intracellularis* be found, repeat the injections daily for the three or four following days; in severe cases give the second dose twelve hours after the first.

4. After the first series of doses, wait two or three days, and if necessary, repeat the series.

5. The serum is a specific and of value in meningococcic meningitis only.

6. It is useless to give the serum subcutaneously.

439 North State Street.

ABSTRACT OF DISCUSSION

DR. CHARLES HUNTER DUNN, Boston: The mortality of this disease at the Children's Hospital in Boston for the past ten years may be interesting. The average number treated was twenty, *i. e.*, cases in which lumbar puncture confirmed the diagnosis of infection with the diplococcus intracellularis. Up to 1902 there was no particular treatment. In 1903-04-05 the condition was treated by repeated lumbar puncture. In 1906 we gave the diphtheria serum a trial, and in 1907 used a vaccine prepared from the diplococcus intracellularis. It was from November, 1907, to November, 1908, that the Flexner serum was first used. During the preceding nine years the mortality had varied from 60 to 80 per cent.—in fact, the mortality was not affected by the treatment. During the last year the mortality dropped to 19 per cent. Dr. Churchill was right in saying that I gave 45 c.c. of serum without getting any spinal fluid. Twice I have seen serious symptoms of collapse in babies from a large dose of the serum without withdrawal of a sufficient amount of fluid.

There are three classes of these fatal cases; first, the fulminating cases, in which the babies die before the serum has time to get in its work; second, the late cases in which so much damage had been done before the serum was given that the patient dies from the injury already inflicted on the nervous system. The third are the resistant cases. There is a type of case in which the organism disappears entirely yet there is no abatement of the symptoms. It has been thought by Flexner that this is due to a complete closure of the canal, as in some of these cases at autopsy there was found within the ventricles an enormous number of organisms. But there are cases in which the serum has practically no effect on the fluid or the symptoms. Recently we had two cases in which no effect at all appeared. I think possibly one explanation of that type of case is that it may be due to a variety of the *Diplococcus intracellularis* that is particularly resistant. Dr. Flexner wants any one who comes across such a case to send him a strain of the organism that he may inject his horses with it and get an effective serum for treatment.

DR. ALFRED HAND, Philadelphia: In the Children's Hospital in Philadelphia we have had but one case of the epidemic form treated with the serum, and this case worked very well. The first day we obtained 45 c.c. of fluid and got the *Diplococcus intracellularis*. On the second day I withdrew 45 c.c. of fluid and injected 30 c.c. of the serum. On the third day I did the same. On the fourth day I could get but 15 c.c. of the fluid and the child was greatly improved. I thought that I was justified in putting in 30 c.c. again and I did so with very little pressure. A couple of hours afterward the child was seized with a violent headache and was screaming with pain, but morphin relieved it, and in five days the child was perfectly well. I have seen cases run on for eleven, twelve, or thirteen months and then the child would die, one occasionally getting well. This case just mentioned was the first case in which we felt that the treatment had had some effect in curing the patient. I felt that there was no harm done by injecting a larger amount of serum.

DR. FRANK ALLEN, Chicago: I have had several cases of cerebrospinal meningitis treated with Flexner's serum. My experience has been much like that of Dr. Churchill. Often lumbar puncture alone would cause the temperature to drop, but without the injection of the serum it would rise again. With the injection of three or four doses of serum the temperature would drop and remain down. In one case in which I could not find the organism the patient died before I could make an injection. Another patient had all the symptoms of pneumonia. On the third day this patient developed cerebral symptoms, puncture showed the diplococcus; the serum was used with almost immediate improvement. In this case we had difficulty in getting out enough fluid. We used 15 c.c., and at one time 30 c.c., without any trouble. The spinal fluid cleared up and no diplococci could be found, but the pneumonia continued and the patient was in the hospital for three weeks with pneumonia, without recurrence of spinal symptoms. In most of the cases the temperature rapidly dropped after treatment.

Dr. William M. Welch, Philadelphia: I have seen Flexner's serum used in a large number of cases of cerebrospinal meningitis in our Municipal Hospital and I regret very much that I have no exact data at hand to show the results. The members of the hospital staff feel sure that the death rate has been considerably reduced by the serum treatment. We have found that it is more useful in the true form of the disease, in which the *Diplococcus intracellularis* is present. But I rise more particularly to speak of an unfortunate result in one instance. The patient was a negro, who was admitted to the hospital with well-marked symptoms of cerebrospinal meningitis. Lumbar puncture was done, but no fluid flowed out. The direction of the needle was changed once or twice, but still no fluid was obtained. It was determined, however, to inject the serum. The patient was sitting in the upright position with his arms and chest resting on the foot of the bed; 15 c.c. were injected without any symptoms, but before the entire contents of the second bottle of 15 c.c. had been used the man complained of severe pain in his head; his head dropped forward and he became unconscious. The respirations were very slow, not more than eight or ten a minute. The breathing was stertorous. The patient never regained consciousness, and died within fifteen or twenty minutes. I should conclude from this experience that it is dangerous to introduce into the spinal canal any considerable amount of the serum without first withdrawing a similar amount of the spinal fluid.

Dr. George D. Scott, New York: It is important to lay particular stress on the fact that the *Diplococcus intracellularis* should be found before the employment of the serum. In the epidemic in New York City some time ago I saw a number of cases in the hospital and in private practice and it was a question often of an absolute diagnosis from lumbar puncture alone. In many cases a wrong diagnosis had been made, sometimes due to the fact that the bacteriologist was not so well informed as he might have been. I find that it is better to inject a small amount of serum more often and not to allow too much of the spinal fluid to escape at each injection. Bearing those points in mind, we can get more benefit from the serum as Dr. Flexner has stated.

Dr. F. S. Churchill: I have had the same experience of injecting more serum than we have removed fluid. I would emphasize what Dr. Scott says that it is of the utmost importance to remember that the serum is a specific. I think I must have been misunderstood by one of the gentlemen. I did not say that the serum was of *more* value in the epidemic form. It is of no value whatever in any other form of the disease. It is a specific for epidemic cerebrospinal meningitis and that fact must be borne in mind. In regard to the unfortunate termination of the case reported from Philadelphia I do not know whether the fact that the patient was sitting up had anything to do with it, but I never have given it to a patient sitting up. In one case of a baby, two years old, where I had employed two successive doses, I used an anesthetic at the third injection. It was a mild case and the baby was pretty thoroughly conscious. I removed the fluid, injected the serum, withdrew my needle and the child seemed all right. But suddenly the breathing stopped and, though we worked with her nearly an hour, she died. In that case the fluid was almost sterile at the last examination. I think I should use gas another time instead of any other anesthetic. We must remember that the serum must be given as early as possible, it must be given in the spinal canal and it must be repeated until the organisms are not found in the spinal fluid.

Practice of Medicine.—The everyday internist can and must be able to practice medicine scientifically. The most important aid to this end is a clinical laboratory properly equipped.—O. I. Halbert, in *Texas State Journal of Medicine.*

HEMOLYSIS OF HUMAN AND RABBIT ERYTHROCYTES BY CROTALUS VENOM *

JOSEPH McFARLAND, M.D., and PAUL G. WESTON, M.D.
PHILADELPHIA

The first studies of the hemolytic action of serpents' venoms seem to have been made by Stevens and Myers,[1] who found that when cobra venom was added to shed blood, *in vitro*, destruction of the corpuscles (hemolysis) and retardation of coagulation took place. They also found the hemolytic power of the venom inhibited by antivenomous serum.

Myers[2] later studied the hemolytic substance—"cobralysine"—of the venom and found it destroyed by heat. During these studies he found that the susceptibility of the erythrocytes to cobralysine *in vitro* bore no relation to the susceptibilty of the animal to subcutaneous intoxication by venom.

Stephens[3] found that the hemolytic constituents of different venoms were not identical.

Myers[4] made further studies of venom hemolysins and serum antihemolysins.

Mitchell and Flexner[5] and Flexner and Noguchi[6] have further studied the phenomena of agglutination, hemolysis, leucolysis, and the germicidal activity of the blood serum. They found that the phenomena of agglutination appeared rapidly in favorable solutions, while in weak solutions a delay of some minutes up to an hour might be noted. Active agglutination took place in 0.2 per cent. solutions, while weaker ones either produce no change at all or show imperfect fusion. They studied corpuscles of the dog, rabbit, guinea-pig, sheep, ox, pig, necturus and frog. The phenomena of hemolysis were found to be complicated. Solutions of 0.2 per cent. were found most favorable for bringing out the hemolytic property, though the different venoms differed considerably, cobra venom being most active, water moccasin, copperhead and rattlesnake venoms less so in the order named. They also found that the corpuscles of different animals differed in their susceptibility to the action of the venom, those of the dog's blood being most easily affected, those of ox blood least so. The intermediate animals in order of susceptibility were sheep, guinea-pig, pig and rabbit. Solutions of 5 per cent. were needed to hemolyze the corpuscles of the ox. Heating to from 75 to 80 degrees C. for 30 minutes does not diminish the hemolytic action of any venom; heating to from 90 to 96 degrees diminishes the activity of rattlesnake venom; heating to 100 degrees C. for fifteen minutes diminishes the hemolytic activity of cobra, moccasin and copperhead venom a little. They believe that venoms contain various intermediate bodies, not all of these being absorbed by any one kind of corpuscles. Venom leucolysis was carefully studied and it was found that venoms contain principles that are agglutinating and dissolving for the white corpuscles of which the agglutinating principle may be identical with those for the erythrocytes. The leucolytic principle is distinct from the hemolytic principle. The several varieties of white cells show different susceptibilities to the action of the venom.

Flexner and Noguchi[7] found that venoms have a cytolytic action on many kinds of cells, probably because of a pleurality of the amboceptors they contain.

Kyes[8] finds that the hemolysis by venom bears a definite relation to the lecithin content of the blood, by which the venom amboceptor is activated.

Noguchi[6] found that the hemolytic principle of venom extended over a wider group of animals than the agglutinative principle, its activity on the bloods of different animals diminishing the more widely the vertebrata were departed from. Cobra venom contains the largest, crotalus venom the smallest number of hemolytic units, while moccasin venom contains the greatest number of agglutinative units for such bloods. The mechanism of hemolysis is identical with that for the bloods of warm-blooded animals; complements are, therefore, present in all vertebrates and in many, at least, of the invertebrates. The heat liability of the venom agglutinins and hemolysins for cold-blooded animals agrees closely with that for warm-blooded animals.

The hemolytic activity of the venoms of the Indian and Australian snakes, and the effects of the antivenomous serums, have been made the subjects of several papers by Lamb.[9]

Throughout the writings to which reference has been made either no mention, or very brief mention is made of the effect of the venoms, and particularly of the rattlesnake venom on human corpuscles. As the rattlesnake is the most common venomous snake of this country, it seemed to us that the effects of its venom on the blood of its most important, though fortunately infrequent victim, man, ought to be investigated, and we set to work accordingly. As in the course of our studies certain facts were brought out confirming or refuting the work of those that preceded us, we feel justified in publishing what we found.

In a previous paper[10] we reported studies made about the same time on the agglutinating effect of crotalus venom on human and rabbit erythrocytes.

The venom used in both series of experiments was obtained for us from the *Crotalus adamanteus* through a special collector in Texas. According to the directions given him, the freshly collected venom was spread out in a thin layer on the surface of clean dinner-plates and dried in the sun. In this way a considerable quantity of excellent dry venom was secured. When the venom was to be employed for making the hemolytic tests, the dry product was finely pulverized, dissolved in the least possible quantity of 0.85 per cent. sodium chlorid solution, filtered through fine filter paper and the filtrate evaporated. The resulting scales were again pulverized, placed in a sterile test tube, covered with chloroform and stood in the thermostat until the chloroform had evaporated through the cotton plug with which the tube was stoppered. Experiments showed that the venom so treated was unmodified as regards hemolytic or agglutinative activity. It was from the powder so prepared that the solutions for hemolysis were made.

The blood was secured from the tip of a thoroughly cleansed finger, the same blood (W.'s) being used in all the tests. By making a deep puncture with a somewhat broad lancet, from one to three cubic centimeters could be secured. The blood was caught in a sterile test tube, immediately defibrinated, then centrifugalized. The serum was removed with a pipette to be used subsequently as serum complement, the corpuscles washed three times in sterile salt solution and finally made into a 5 per cent. suspension in 0.85 per cent. sodium chlorid solution.

In making the hemolytic tests, 1 c.c. of the corpuscular suspension was placed in each of a series of tubes suitable for use in the centrifuge, 0.5 c.c. of a mixture of one part of normal human serum (that removed with the pipette from the centrifuge tube as mentioned above) and two parts sterile saline solution and varying quantities of venom added. The mixture was shaken gently and enough saline solution added to bring up the volume to 2 c.c. The tubes were then stood in the thermostat at 37 degrees C. for one hour, when the first observation was made. They were then again gently shaken and placed in the icebox over night, after which the final observations were made by whirling the tubes for 5 minutes in the centrifuge and then examining the clear fluid for variations in the color tint.

In the tabulations we express the occurrence of hemolysis by the letter H, doubling or trebling the letters to express the degree. "H?" means doubtful hemolysis or a very faint trace. "HC" means complete hemolysis. We also exhibit the associated agglutination by the use of the letter A. The amount and character of the sediment is, in general, perhaps, a better index to the amount of hemolysis. In these experiments the sediments in tubes marked H were all the same, those in tubes marked HH were the same but different than those in tubes H or HHH, so that, whether the tints or sediments were used as indices, the results would be the same.

The quantity of venom has been expressed by some of those who experimented with the hemolytic reactions in the form of percentages, but, as these vary according to the final dilution of the mixture, and as after some experiments we were obliged to increase from a 2 c.c. to a 10 c.c. mixture, we believe it to be more accurate to express the quantity of venom in the form of grams of the dry venom in the final mixture.

TABLE 1.—Two Cubic Centimeter Dilutions

Grams dry venom of *Crotalus adamanteus* in total quantity of final mixture.	%		Normal human erythrocytes from defibrinated blood susp. in 0.85 % NaCl sol., (5% susp.)		Normal human serum diluted with 2 vols. normal NaCl solution.		Results.
0.001	(.05)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.005	(.25)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0 01	(.5)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.0125	(.625)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.03	(1.5)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.05	(2.5)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHH
0.06	(3)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHH
0.2	(10)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H

TABLE 2.—Two Cubic Centimeter Dilutions

0.01	(5)	plus	1 c.c.	plus	1.0 c.c.	equals	A plus O
0.04	(2)	plus	1 c.c.	plus	1.0 c.c.	equals	A plus H

Table 1 shows that increasing additions of venom result in increasing hemolysis until a certain point is reached. Beyond this point added venom diminishes the hemolytic activity, presumably because of excess of amboceptor units in the venom. Table 2 shows that the same disturbance results from excess of complementary units; when 1 c.c. of the serum dilution, instead of the 0.5 [illegible] Table 1, is used, hemolysis is greatly [illegible] in Table 1, 0.01, 0.03 and 0.05 grams of venom produce marked hemolysis, but in Table 2, 0.01 causes no hemolysis and 0.04 very slight hemolysis.

Whether these results depend on the Neisser-Wechsberg phenomenon seems to us to be problematical.

[10] Read at the meeting of the American Association of Pathologists and Bacteriologists, Boston, April 9-10, 1909.

We soon found it impracticable to continue to work with 2 c.c. mixtures, because of the difficulty of dissolving the necessary quantity of venom in the small quantity of fluid used. We were, therefore, obliged to change to a 10 c.c. mixture. In this mixture we deal with the same number of corpuscles, the same quantity of serum and the same quantity of venom, though, of course, the percentage of venom is changed by the dilution. This made us abandon the percentage expression and make use of figures indicative of the actual weight of dry venom added to the mixture.

Table 3 shows the details of experiments made with the 10 c.c. mixture for comparison with those in Table 1 in which 2 c.c. mixtures were employed. It will be seen that the results are the same. This was to be expected, as the proportions were the same. The percentages of venom are, however, entirely different.

TABLE 3.—TEN CUBIC CENTIMETER DILUTIONS

Grams of dry venom of *Crotalus adamanteus* in total quantity of final mixture.	%		5% susp. of normal human erythrocytes from defibrinated blood, in 0.85% NaCl solution.		Normal human serum diluted with 2 vols. normal NaCl solution.		Results.
0.01	(0.1)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.03	(0.3)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.05	(0.5)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHH
0.07	(0.7)	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHHH

TABLE 4.—TEN CUBIC CENTIMETER DILUTIONS

		Corpuscles from citrated blood.		Citrated plasma.		
0.01	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.03	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.05	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.07	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHH

In our paper on the agglutination of the corpuscles, we have shown that it makes considerable difference in the rapidity with which the reaction takes place whether defibrinated or citrated blood is used to furnish the corpuscles.

In investigating this problem with reference to hemolysis we used the following technic:

The blood from the finger tip was permitted to flow into a sterile tube containing sterile sodium citrate solution (2 per cent. in 0.85 per cent. sodium chlorid solution). The fluids were well mixed, then centrifuged, the supernatant fluid removed with a pipette to be used in lieu of the serum ordinarily employed and the corpuscles washed three times as usual, then made into a 5 per cent. suspension.

One c.c. of the suspension was placed in each of a series of tubes, varying quantities of venom were added, and to each was added a quantity of the citrated plasma shown by calculation to be the equivalent of the 0.5 c.c. of the serum mixture ordinarily employed. Thus the conditions, after dilution to 10 c.c., were identical with the other experiments except that the corpuscles had been acted on by the sodium citrate and a small quantity of sodium citrate remained mixed with the plasma. The experiment in Table 4 shows that the hemolysis is slightly less when the citrated corpuscles are employed for the test. Thus the effect of the citrate is to diminish hemolysis and to retard agglutination, using defibrinated blood as a standard.

In order to compare our results with some known quantity, we next made a series of tests in which rabbits' corpuscles instead of human corpuscles were employed.

Table 5 shows the hemolytic effect of the crotalus venom on rabbit erythrocytes from defibrinated and citrated blood. As in the human blood, there is a diminution in the amount of hemolysis when the citrate is employed. It will also be observed that the defibrinated rabbit corpuscles are about ten times as sensitive to the hemolytic action of the venom as are the citrated corpuscles.

TABLE 5.—TEN CUBIC CENTIMETER DILUTIONS: RABBIT

Grams of dry venom of *Crotalus adamanteus* in total quantity of mixture.		5% susp. of norm. erythrocytes from defibrinated blood in 0.85% NaCl solution.		Normal rabbit serum diluted with 2 vols. of NaCl solution.		Results.
0.0000125	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H
0.000125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.00125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.0125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HHH
		RABBIT: 5% susp. of normal erythrocytes from citrated blood in 0.85% NaCl sol.				
0.0000125	plus	1 c.c.	plus	0.5 c.c.	equals	O plus O
0.000125	plus	1 c.c.	plus	0.5 c.c.	equals	O plus O
0.00125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.0125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH
0.125	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH

Flexner and Noguchi found that when venom was heated to from 75 to 80 degrees C. the hemolytic properties were not affected. As no mention was made of the state in which the venom was heated, we decided to try whether the fact was true both of pulverized dry venom and of venom in solution.

To test the effect of heating it in the dry state, a small quantity was spread on the bottom of a small Erlenmeyer flask and floated on a water bath which was kept for 30 minutes between 75 and 80 degrees C. The powder was then dissolved and hemolytic tests made on both human and rabbit corpuscles. The results of the experiments are shown in Tables 6 and 7. When Table 6 is compared with Table 5, it becomes evident that heating the venom, even in the dry state, produces a marked diminution of the hemolytic activity, for in Table 5 hemolysis is distinct in 10 c.c. mixtures when only 0.0000125 grams of venom are added, though in Table 6 hemolysis begins only after 0.002 grams of the heated venom have been added. The same result was obtained with both defibrinated and citrated serums.

TABLE 6.—VENOM POWDER HEATED DRY FOR 30 MINUTES AT 75° TO 80° C.

Grams of dry venom of *Crotalus adamanteus* in total quantity of final mixture.		5% susp. of rabbits' erythrocytes, from defibrinated blood in 0.85% NaCl solution.		Normal rabbit serum diluted with 2 vols. 0.85% NaCl solution.		Results.
0.002	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H(?)
0.01	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H
0.03	plus	1 c.c.	plus	0.5 c.c.	equals	A plus HH

TABLE 7.—VENOM POWDER HEATED DRY FOR 30 MINUTES AT 75° TO 80° C.

		5% susp. of normal human erythrocytes from defibrinated blood in 0.85% NaCl solution.				
0.002	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H(?)
0.01	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H (slight)
0.03	plus	1 c.c.	plus	0.5 c.c.	equals	A plus H (slight)

When human corpuscles were employed the effect of heating the venom was much less marked. Thus when Table 3 is compared with Table 7 it will be seen that the unheated venom produces hemolysis when quantities of 0.01 gram and upward are added, and becomes marked when 0.03 grams are reached, though when the heated venom is added the hemolysis effected by 0.01 is very slight and with 0.03 is still very slight. Experiments made with citrated blood showed the same result.

It thus becomes apparent that there is a difference in the hemolytic activity of the heated and unheated venoms for rabbit and human corpuscles.

This led us to conjecture that the hemolytic factors for these different corpuscles might be different, but this we were unable to prove.

When the venom was first dissolved and then heated, the heating being accomplished in the same manner, by placing the solution in a small Erlenmeyer flask and floating it on a water bath kept for 30 minutes at between 75 and 80 degrees C., a much more pronounced destruction of the hemolytic power was brought about.

The results are shown in Table 8. When human corpuscles are exposed to unheated venom solutions, as shown in Table 1, hemolysis begins when 0.001 grams are added: when the venom solution is heated, when 0.002 grams are added. If, however, *rabbit corpuscles* are used, the results are entirely different, for when the unheated solution is employed, hemolysis begins (Table 5) at 0.0000125 grams, but when the solution is heated at 0.002 grams. Practically the same diminution of hemolysis takes place whether defibrinated or citrated blood is used.

TABLE 8.—Venom Solutions Heated for One-Half Hour at 75° to 80° C.

Grams of dry venom of *Crotalus adamanteus* in total quantity of final mixture.		5% susp. of normal human erythrocytes in 0.85% NaCl solution.		Normal human serum diluted with 2 vols. of saline solution.		Results.
0.00001	plus	1 c.c.	plus	0.5 c.c.	equals	O plus O
0.0005	plus	1 c.c.	plus	0.5 c.c.	equals	O plus O

0.002	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H(?)
		5% susp. of normal rabbits' corpuscles from defibrinated blood in 0.85% NaCl solution.				
0.0002	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H?
0.0005	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H?
0.001	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H?
0.0015	plus	1 c.c.	plus	0.5 c.c.	equals	O plus H

We observed an interesting change in the hemoglobin of the corpuscles not hemolyzed.

If the corpuscles from a tube containing venom and serum in quantities too small to effect hemolysis be collected by centrifugalization and suspended in fresh 0.85 per cent. sodium chlorid solution, the corpuscles remain unchanged. If again collected and again suspended in fresh saline solution, a change may or may not be seen; but if the operation be repeated a third time the corpuscles undergo immediate hemolysis in the salt solution.

In the course of some immunization experiments that turned out badly, we prepared a venom solution by dissolving the dry venom in 100 parts of 0.85 per cent. sodium chlorid solution and then saturating it with chloretone. This prevented bacterial contamination and the toxic properties of the venom were preserved for considerable time. On using this solution for a hemolytic test, we found complete hemolysis in 30 minutes when it was not expected. We then tried a saturated solution of chloretone in the normal salt solution, and found that the antiseptic itself caused rapid and complete hemolysis when in saturated solution. We were thus led to abandon the use of chloretone for preserving the venom solutions.

As human blood in quantities sufficient to furnish enough corpuscles for making hemolytic tests is not easily obtained, we were interested to determine how long the corpuscles, once suspended in the saline solution, might be available for use. Suspensions (5 per cent.) of both human and rabbit corpuscles were, therefore, prepared and kept in the icebox, being subjected to hemolytic tests from time to time. We found that during 24 hours there was very little change, but that after 36 hours hemolysis took place much more rapidly than before.

From this we came to the conclusion that the corpuscular suspensions should be prepared every day and not kept over, and the experiments we report were always made on freshly secured blood.

In order to study the effects of crotalus venom on the leucocytes, we made use of the sediments collected by centrifugating the tubes in which hemolysis had taken place. This was spread on slides and stained by the Romanowsky method. All these observations were, therefore, made on corpuscles that had been in contact with the venom in the icebox for 24 hours, and do not form very satisfactory data.

We found that the small lymphocytes stained well and appeared quite normal even in tubes to which as much as 0.07 grams of venom had been added.

Large lymphocytes were apparently unaffected by quantities of venom less than 0.03 grams per 10 c.c. of fluid. They were not found in tubes containing 0.03 grams and upward.

The polymorphonuclear neutrophiles showed the most marked changes, and are, therefore, probably the most susceptible to the cytolytic action of the venom. Even small quantities of the venom produced marked karyolysis with a hyaline change of the cytoplasm. This is an interesting observation which may have some bearing on the invasion of the tissues by bacteria which so quickly takes place after venom injection.

The eosinophiles seemed to resist the venom very well. In no case, even up to the addition of 0.07 grams to the 10 c.c. mixture, were they completely destroyed, though the nuclei refused to stain. The granules were never destroyed. No basophilic cells were found in any of the sediments.

CONCLUSIONS

1. Crotalus venom is capable of hemolyzing red corpuscles of both man and the rabbit in the presence of serum or of citrated plasma.

2. When an excess of the venom, or an excess of the serum is present, hemolysis diminishes.

3. In the properly proportioned mixtures, hemolysis takes place regardless of the extent to which the mixtures may be diluted by the addition of salt solution.

4. Defibrinated blood furnishes corpuscles more sensitive to the venom than citrated blood.

5. Heating dry venom diminishes its hemolytic activity for human corpuscles a little, for rabbit corpuscles a great deal.

6. Heating solutions of venom diminishes its activity for human corpuscles a little, for rabbit corpuscles a great deal.

7. Rabbit corpuscles are much more susceptible to the hemolytic effect of the venom than human corpuscles.

8. Corpuscles in suspension should not be kept from day to day for venom experiments.

9. The small lymphocytes and eosinophiles resist the venom better than the large lymphocytes and polymorphonuclear neutrophiles.

ABSTRACT OF DISCUSSION

DR. D. H. BERGEY, Philadelphia: Presumably, from the manner in which the experiments have been conducted, the hemolysis brought about by the venom is due to the presence in it of an amboceptor; and the addition of serum to the mixture of venom and blood supplies the complement. How do the authors of the paper explain the disappearance of hemolytic power, since we know that amboceptors are supposed to be thermostabile?

DR. E. C. L. MILLER, Detroit: Is there any especial explanation for the fact that venom acts in proportion to the absolute quantity present and not in proportion to the dilution, as it forms, in this respect, an exception to the ordinary rule?

DR. JOSEPH MCFARLAND, Philadelphia: When we found that it was necessary to change from a mixture containing only 2 c.c. to one containing 10 c.c., the question of the relation of proportion to quantity arose, and we discovered that, as shown by a comparison of tables, the increase in quantity had no effect at all on the action of the venom. Then I suggested that it would be interesting to try still higher dilutions, which we did; and we found no change in the behavior of mixtures of 250 c.c., the largest amount used, hemolysis taking place in this the same as in smaller quantities. I cannot answer Dr. Bergey's question quite so positively. Just what the loss of hemolytic power in the heated venom indicates, I do not know. It might indicate that the amboceptors were in a different class from the ordinary bacteriolytic or hemolytic amboceptors. I scarcely think, however, that this would be the case. I believe tnat it is true that heating disturbs all amboceptors somewhat and that the virulence is diminished in proportion to the amount of heat and the length of time in which the heating takes place.

DR. D. H. BERGEY: I believe that this is true, but do not think that it is true to the extent that it has been found in your experiments.

DR. MCFARLAND: The disturbance affected about half its virulence in this case.

SOME POINTS OF CONTACT BETWEEN NEUROLOGY AND ORTHOPEDIC SURGERY *

JOEL E. GOLDTHWAIT, M.D.
BOSTON

It is the purpose of this paper to call attention to a few of the more recently understood conditions which produce symptoms for which either the neurologist or the orthopedic surgeon may be consulted and where frequently the methods peculiar to both specialties are of advantage in bringing about relief. It is not proposed to discuss the many problems in which the two specialties have been for long correlated, such as the treatment of the infantile or spastic paralyses, as there is little new to add to such subjects, even if the time were sufficient, and in those which are considered the time is so short that only a brief mention of them is possible. It is the hope, however, that the statements here made may serve as suggestions which will lead to a more thorough investigation of the conditions so that an even better understanding of their various phases may be obtained. The honor of being permitted to speak before such a body as this is fully appreciated, and it is my earnest hope that that which is presented may be of sufficient value to justify the amount of time allotted.

SPINAL LESIONS

In a considerable number of lesions of the spine, other than tuberculous, the inflammatory swelling or the osseous thickening which is a part of such diseases frequently causes pressure on or irritation of the nerve roots and results in symptoms referred to the portion of the body that the irritated nerve supplies. These symptoms may consist of pain, at other times areas of hyperesthesia or anesthesia, or even at other times true paralysis, the exact symptoms depending on the special nerve involved and the amount of pressure or irritation present.

Such a condition may result from the involvement of any region of the spine, but naturally in the regions of the greatest mobility, the cervical and lumbar, they will be most often met. The symptoms present in the given case must, therefore, depend very largely on the region of the spine involved. In the cervical region the symptoms will naturally be referred to the neck or arms or to the areas supplied by the cervical or brachial plexuses. In the dorsal region, aside from the symptoms present at the seat of the disease, the pain referred along the course of the intercostal nerves is the most common. In the lumbar region the referred pain may show in any part supplied by the lumbar and sacral plexuses, the low back or abdomen, the pelvis or perineum, or any part of the legs.

Whenever such spinal conditions exist the referred symptoms, those which most often lead to the consultation of the neurologist, are almost invariably either entirely on one side or at least much more marked on one side than on the other. With the dorsal or lumbar spinal lesions the unilateral manifestation is almost always the case, but in the cervical region, while one side is always worse, nevertheless both sides are usually somewhat involved.

The symptoms are always, if the disease is at all acute, aggravated by sudden movement of the affected part, such as in coughing or sneezing, slipping or any unguarded motion. With lesions in the lumbar or in the cervical spine the pain is commonly worse at night because of the opportunities offered for sag of these portions of the spine with the relaxation of the muscles, such as takes place during sleep.

Of the special diseases which may cause symptoms of this sort it is not possible in so short a time to do more than briefly to mention them, and the reader must refer to the various articles published elsewhere for further details. The most common, however, are the chronic infectious arthritis and the hypertrophic arthritis, but it should be remembered that any disease in which there is inflammatory swelling or thickening about the vertebral articulations may result not only in symptoms referred directly to the seat of the disease, but also to symptoms referred to other parts, owing to the pressure on or irritation of the nerve roots. With the two most common conditions, the infectious arthritis is the more acute, and the local symptoms are the most pronounced. There is more local swelling, which in the cervical spine can often be felt, and the muscular spasm causing the limitation of the motion is much more marked than with the hypertrophic arthritis. The referred pains are more sudden in their development and more acute, both in regard to the intensity of the pain as well as the duration. The recovery in such a type of disease should be correspondingly rapid and is usually complete.

With the hypertrophic arthritis the process is slow in its onset and there may be an entire absence of subjective symptoms at the seat of the disease. The referred symptoms have so little else to show for them that the real nature of the trouble is apt to be overlooked unless the examination be most thorough. In this type not only is the onset slow, but the recovery is correspond-

inly slow, and it is in this type at times that the thickening which causes the pressure on the nerves is so marked and so dense that complete restoration of the function may never occur.

The following cases are reported as illustrative of these forms of disease:

Case 1.—Hypertrophic arthritis of the cervical spine resulting in sufficient pressure on the cervical and brachial plexuses to cause paralysis of the arms.

Patient.—Mrs. McC., aged 58, by occupation a nurse, had always been well and actively engaged in her work until the present sickness. In July, 1893, she was caught in a thundershower and her clothing was wet through. The next morning she complained of pain in the neck, with some tenderness in the upper part of the chest. There was no cough or expectoration. The pain in the neck increased in severity very rapidly, until the slightest motion caused the most intense suffering, and because of this she was admitted to the Good Samaritan Hospital.

Examination.—At the time of the first examination she was evidently suffering a good deal. The head was held a little to one side, the chin to the left, the shoulders drawn up, and all motions were most carefully guarded by muscular contraction. Any attempt at motion caused great pain. None of the other joints were in the last involved, and aside from this local condition the patient seemed well.

Treatment and Course of Disease.—For the first week or two the patient was kept quiet in bed, and the various rheumatic remedies freely given with very little if any effect. After this a Thomas collar was applied for more complete fixation, and following this light-weight extension was used. These gave some relief, but neither could be used continuously because of the nervousness of the patient, so that the two applications were used alternately, each being worn for a few hours. In three or four weeks after the beginning of the attack a swelling appeared in the right side of the neck. This was about the size of a small lemon, and was apparently connected with the spine. At the same time numbness of the left arm was noticed, with some impairment of motion, and this condition continued and increased until the arm was almost entirely helpless. The right arm and both legs also became involved, never in as marked a degree as the left arm, but enough to make motion in bed, unassisted, impossible. At one time there was difficulty in swallowing, and for a short period breathing was almost entirely diaphragmatic. The patient's condition remained about the same for two months, after which there was a slow but steady improvement, so that at the end of the third month she was able to sit up for a short time each day, and in December, five months from the onset of the trouble, she was able to move about with but little assistance, and was taken home. The paralytic symptoms referred to in the right arm and legs had by this time practically disappeared, but the left arm was still very helpless. The swelling in the neck was practically the same as when first noticed.

Later History.—The patient was not again seen until thirteen months later, during which time, aside from the use of the Thomas collar, no special treatment had been carried out. At the time of this examination the improvement in the patient's general condition was most marked. She moved about with perfect ease, and, aside from the stiffness of the neck and some impairment in the use of the left arm, she seemed well. Extension of the neck was entirely restricted, so that in order to raise the chin the whole body was bent backward. Rotation was also entirely restricted, while flexion was more free, it being possible to lower the chin to the chest. On each side of the neck, over the tranverse processes, was distinct thickening. In the left arm all motions were limited, especially those in which the shoulder muscles were used. The fingers were flexed, apparently owing to the contraction of the palmar fascia and the flexor tendons. The sensation of the hand and arm was normal. At the present time the patient's condition is practically the same as at the time of this last note. She is able to be about at her work, but there has been no change in the condition of the neck or arm.

Case 2.—Infectious arthritis of the cervical spine with paralysis of the arms due to nerve root pressure.

Patient.—Mr. E., aged 38, was seen in January, 1900, having had rheumatism for many years, but no one part being especially involved and the disease never being severe enough to confine him at home for more than short periods. For the year previous to the first examination the patient had had trouble with the shoulder, which had gradually extended to the neck. At the time of the examination the entire cervical spine was actually inflamed, all motions being extremely painful. At that time the left arm was much limited in its function; not only was it painful but there was a partial paralysis of the muscles. Under observation the paralysis of the arm increased until it was practically entirely helpless, it being necessary to raise the hand and place it in whatever position was desired. The right arm became considerably involved, but less markedly so than the left.

Diagnosis.—The condition represented an infectious arthritis (the so-called "rheumatism"), which had involved the cervical spine, and with the periarticular swelling the nerve roots had been constricted until a partial paralysis of the arms resulted.

Treatment and Course of Disease.—Under good hygiene, having the patient live out of doors, much as would be insisted on in a tuberculous case, with a Thomas collar to steady the head and neck, and with rational drug treatment, the patient gradually recovered, and in six months had regained the full function of the arm, with only slight remaining limitation of motion in the neck. With the general instruction as to hygiene the patient has remained well with no further trouble.

Case 3.—Hypertrophic arthritis of the cervical spine with temporary paralysis of the shoulder and arm muscles.

Patient.—G. H., a man, aged 32, consulted me in September, 1898. He was a professor in one of our large universities. His family history was excellent; he had been well previous to January, 1897, when he broke down nervously. He went abroad, and soon after this stiffness of the neck and shoulders developed, not enough, however, to prevent his going about. Soon after this, numbness developed in the left arm, with marked loss of power, and later the right arm was similarly involved, only not so severely. The condition improved slightly, and then remained about as it was at the time of the examination. At that time there was a moderate rounded curve involving the upper dorsal cervical regions of the spine. This portion of the spine was rigid. The shoulders were drooped forward and there was atrophy of the muscles of the chest, shoulders, and upper back. On attempted motion there was spasm of the muscles about the shoulders and upper spine. The legs were normal and there was no change in the reflexes. There was marked loss of power in the left arm, with some numbness, and there was a tendency to the same condition on the right side.

Treatment.—This consisted almost wholly of support of the cervical spine, which was used for a few months and was followed by entire recovery, except for slight permanent limitation of motion of the neck.

Case 4.—Hypertrophic arthritis of the cervical spine with arm symptoms.

Patient.—Mary S., aged 35, came to the Carney Hospital about three years ago because of trouble with the back and neck. The history as given was that a few months previously she made a change in the underclothing and took cold. This was followed by pain in the neck which prevented her from being about. At that time the slightest motion of the head was extremely painful. No other joints were involved. The arms for some time could not be used freely, the left one being worse. Under general treatment, with fixation of the neck, the patient gradually improved, so that at the present time, except for the rigidity of the upper dorsal and lower half of the cervical spine, she is well.

Case 5.—Hypertrophic arthritis with irritation of the intercostal nerves causing the so-called intercostal neuralgia.

Patient.—Mr. R., was first seen in August, 1900, because of a persistent pain in the left side, a condition which had been present for nearly a year, which had not yielded to drugs or other forms of treatment, and which had been so persistent and interfered so much with the ordinary activities that the patient, who was an active business man, had practically decided to retire from all active life. The back was rounded forward, there was limitation of motion in the lower dorsal and lumbar regions, the motions of the spine increased the pain along the line of the intercostal nerves, and sudden movements, such as coughing or sneezing, increased it markedly. The case was one of hypertrophic arthritis of the dorsal spine with pressure on and irritation of the intercostal nerves.

Treatment.—A jacket was applied holding the body erect and relieving the irritation of the dorsal spine consequent on motion, with immediate relief and with entire recovery in a few months. The patient remained well after that time.

SACROILIAC LESIONS

Undoubtedly the most common joints to show lesions of any sort are those between the ilia and the sacrum, since these joints are supported entirely by muscles and ligaments, and consequently anything which interferes with the tone of those may lead to strain of the joints or sag or displacement of the bones; and since the sacral plexus of nerves passes directly over these joints, it is not to be wondered at that in many of such cases pain is present, due to the irritation of some portion of this plexus. Undoubtedly more of the cases of sciatica are due to this than to any other one thing, and in such cases not only may pain be present, but the continued irritation of the nerve may lead to an exaggeration of the reflexes, or, if the pressure is severe enough, actual paralysis may exist.

The location of such pain naturally varies and depends on the amount of or the portion of the plexus that is irritated. It may be quite general and extend the length of the leg, or it may be confined to definite areas, there being areas of hyperesthesia or anesthesia. The symptoms will be increased by motion in the affected joint, and are almost invariably worse at night or when the body is for long in the recumbent position, during which time the supporting muscles relax. With this relaxation the lumbar spine is allowed to sag and thus drags the upper part of the sacrum backward, producing strain of the joint with resulting pain, either local or referred.

The increase in the pain in sciatica when the patient is in bed and the common custom in such cases of sleeping in a chair in the semierect position is to be explained in this way.

Case 6.—Weakness of the sacroiliac joints following injury and acute illness, with ultimate displacement of the sacrum, this causing obstinate sciatica.

Patient.—Miss S., had been an invalid for fifteen years, suffering much from sciatica, with backache and neuritis of the right arm. The history is that seventeen years previous to her being seen she fell over some stairs, striking the lower part of the back, being quite lame for a short time, with considerable pain referred to the lower back. Two years later she had an acute illness, with a high temperature which lasted for a few days. After this a severe backache developed, with pain in the right leg, and ever since then the patient had pain in the leg, called sciatica, with continued backache, and in practically all of that time was an invalid. The menstrual period was attended with marked increase of pain.

Examination.—The patient was in extremely poor general condition, with extreme tenderness over the region of the sacrum and especially the sacroiliac articulations. She was able to walk only with the use of a cane, and any motion of the lumbar spine or of the thighs which produced motion or strain of the pelvic joints caused an increase of the pain. The straight leg raising, in which the hamstring muscles are made tight, was exceedingly painful and allowed to only a few degrees. There was much pain referred to the arms and hands, increased or relieved by posture. The history suggested weakening of the sacroiliac joints at the time of the injury, with a relaxation of the joints at the time of the acute illness, and the displacement of the sacrum backward at that time, the sciatica representing the irritation of the sacral plexus consequent on the displacement of the bone. The pain of the arm, neuritis, was due to the extreme forward position of the shoulder, a part of the weakened condition, and the crowding of the brachial plexus against the ribs by the head of the humerus.

Treatment and Course of Disease.—The sacroiliac joints were manipulated under an anesthetic, the sacrum was forced into place with a marked temporary increase of the sciatic pain, but with a marked relief almost at once in the general nervous tension. With the aid of supports, consisting first of the adhesive plaster strapping, later on of the pelvic belt and a flexible back brace, the patient was able to get about, and has gradually regained her health, with nearly the normal return of the functions of the body. With the change in the posture and the holding of the shoulder back the pain in the arms has disappeared.

Case 7.—Obstinate sciatica due to displacement of the sacrum.

Patient.—Mr. A., aged 19, midshipman at Annapolis, had been under active treatment and away from his duties for the past ten months because of severe sciatica in the right leg. The trouble came on suddenly and persisted and caused much suffering ever since. In that time the patient had all sorts of treatment, including injections along the nerve sheath, massage, long periods of rest, drugs, etc., with no improvement.

Examination.—The patient stood with the muscles of the spine and thighs all in marked spasm, with the body listed to the left, with forward bending and side bending markedly limited, with the spinal motions much more free when sitting, in which position the hamstring muscles are relaxed, with the hip motions free except the straight leg raising, this being almost entirely limited on the left side, and considerably limited on the right, with marked tenderness over the sacroiliac articulations. The case was one of backward displacement of the sacrum on the left side, with the sciatica resulting from the irritation of the sacral plexus.

Treatment and Course of Disease.—The patient was admitted to the hospital and the joints manipulated, but the replacement of the bone could not be accomplished at that time. Plaster-of-Paris jackets were applied and other forms of spinal support without relief, and three weeks later another manipulation was attempted, this time with a distinct slip of the bone into place, with immediate relief of the sciatica. A few days later the patient left the hospital, and on the way across the city the bone slipped slightly out of place, with an instant return of the sciatic pain, which was at once corrected by the application of a brace which forced the bone back into place. Since then, with the use of a pelvic belt, there has been no further difficulty. There has been no return of the pain.

Case 8.—Severe sciatica due to displacement of the sacrum and with severe brachial neuralgia due to the forward position of the shoulder.

Patient.—Miss W., aged 28, was seen four years ago because of severe sciatica which had been present off and on for four years. In that time the patient had had much backache and the sciatica had been so constant, making sleep difficult, that the patient had become very nervous and was in a marked neurasthenic state.

Treatment and Course of Disease.—From the attitude assumed in standing and the motion allowed, together with the tenderness over the sacroiliac joints, a lesion of these joints was diagnosed and fixation apparatus applied, but entirely without relief. Manipulation was then attempted and resulted in a marked slip of the sacrum into place, with instant relief to the pain, with an immediate ability to go about, with a rapid disappearance of the neurasthenic symptoms, and an entire relief of symptoms ever since. A belt was worn for a few months following the manipulation. The patient also complained much of pain in the arms, chiefly the right, which interfered much with all function and which caused much suffering at night. This persisted after the sciatica was relieved by the manipulation and in an attempt to control it she was at one time confined to bed for three months under the care of most competent physicians, but without relief. Recognizing later that the pain in the arm was due to the crowding of the brachial plexus by the head of the humerus in the forward position and that this forward position was held by adhesions inly slow, and it is in this type at times that the thickening which causes the pressure on the nerves is so marked and so dense that complete restoration of the function may never occur.

The following cases are reported as illustrative of these forms of disease:

Case 1.—Hypertrophic arthritis of the cervical spine resulting in sufficient pressure on the cervical and brachial plexuses to cause paralysis of the arms.

Patient.—Mrs. McC., aged 58, by occupation a nurse, had always been well and actively engaged in her work until the present sickness. In July, 1893, she was caught in a thundershower and her clothing was wet through. The next morning she complained of pain in the neck, with some tenderness in the upper part of the chest. There was no cough or expectoration. The pain in the neck increased in severity very rapidly, until the slightest motion caused the most intense suffering, and because of this she was admitted to the Good Samaritan Hospital.

Examination.—At the time of the first examination she was evidently suffering a good deal. The head was held a little to one side, the chin to the left, the shoulders drawn up, and all motions were most carefully guarded by muscular contraction. Any attempt at motion caused great pain. None of the other joints were in the last involved, and aside from this local condition the patient seemed well.

Treatment and Course of Disease.—For the first week or two the patient was kept quiet in bed, and the various rheumatic remedies freely given with very little if any effect. After this a Thomas collar was applied for more complete fixation, and following this light-weight extension was used. These gave some relief, but neither could be used continuously because of the nervousness of the patient, so that the two applications were used alternately, each being worn for a few hours. In three or four weeks after the beginning of the attack a swelling appeared in the right side of the neck. This was about the size of a small lemon, and was apparently connected with the spine. At the same time numbness of the left arm was noticed, with some impairment of motion, and this condition continued and increased until the arm was almost entirely helpless. The right arm and both legs also became involved, never in as marked a degree as the left arm, but enough to make motion in bed, unassisted, impossible. At one time there was difficulty in swallowing, and for a short period breathing was almost entirely diaphragmatic. The patient's condition remained about the same for two months, after which there was a slow but steady improvement, so that at the end of the third month she was able to sit up for a short time each day, and in December, five months from the onset of the trouble, she was able to move about with but little assistance, and was taken home. The paralytic symptoms referred to in the right arm and legs had by this time practically disappeared, but the left arm was still very helpless. The swelling in the neck was practically the same as when first noticed.

Later History.—The patient was not again seen until thirteen months later, during which time, aside from the use of the Thomas collar, no special treatment had been carried out. At the time of this examination the improvement in the patient's general condition was most marked. She moved about with perfect ease, and, aside from the stiffness of the neck and some impairment in the use of the left arm, she seemed well. Extension of the neck was entirely restricted, so that in order to raise the chin the whole body was bent backward. Rotation was also entirely restricted, while flexion was more free, it being possible to lower the chin to the chest. On each side of the neck, over the tranverse processes, was distinct thickening. In the left arm all motions were limited, especially those in which the shoulder muscles were used. The fingers were flexed, apparently owing to the contraction of the palmar fascia and the flexor tendons. The sensation of the hand and arm was normal. At the present time the patient's condition is practically the same as at the time of this last note. She is able to be about at her work, but there has been no change in the condition of the neck or arm.

Case 2.—Infectious arthritis of the cervical spine with paralysis of the arms due to nerve root pressure.

Patient.—Mr. E., aged 38, was seen in January, 1900, having had rheumatism for many years, but no one part being especially involved and the disease never being severe enough to confine him at home for more than short periods. For the year previous to the first examination the patient had had trouble with the shoulder, which had gradually extended to the neck. At the time of the examination the entire cervical spine was actually inflamed, all motions being extremely painful. At that time the left arm was much limited in its function; not only was it painful but there was a partial paralysis of the muscles. Under observation the paralysis of the arm increased until it was practically entirely helpless, it being necessary to raise the hand and place it in whatever position was desired. The right arm became considerably involved, but less markedly so than the left.

Diagnosis.—The condition represented an infectious arthritis (the so-called "rheumatism"), which had involved the cervical spine, and with the periarticular swelling the nerve roots had been constricted until a partial paralysis of the arms resulted.

Treatment and Course of Disease.—Under good hygiene, having the patient live out of doors, much as would be insisted on in a tuberculous case, with a Thomas collar to steady the head and neck, and with rational drug treatment, the patient gradually recovered, and in six months had regained the full function of the arm, with only slight remaining limitation of motion in the neck. With the general instruction as to hygiene the patient has remained well with no further trouble.

Case 3.—Hypertrophic arthritis of the cervical spine with temporary paralysis of the shoulder and arm muscles.

Patient.—G. H., a man, aged 32, consulted me in September, 1898. He was a professor in one of our large universities. His family history was excellent; he had been well previous to January, 1897, when he broke down nervously. He went abroad, and soon after this stiffness of the neck and shoulders developed, not enough, however, to prevent his going about. Soon after this, numbness developed in the left arm, with marked loss of power, and later the right arm was similarly involved, only not so severely. The condition improved slightly, and then remained about as it was at the time of the examination. At that time there was a moderate rounded curve involving the upper dorsal cervical regions of the spine. This portion of the spine was rigid. The shoulders were drooped forward and there was atrophy of the muscles of the chest, shoulders, and upper back. On attempted motion there was spasm of the muscles about the shoulders and upper spine. The legs were normal and there was no change in the reflexes. There was marked loss of power in the left arm, with some numbness, and there was a tendency to the same condition on the right side.

Treatment.—This consisted almost wholly of support of the cervical spine, which was used for a few months and was followed by entire recovery, except for slight permanent limitation of motion of the neck.

Case 4.—Hypertrophic arthritis of the cervical spine with arm symptoms.

Patient.—Mary S., aged 35, came to the Carney Hospital about three years ago because of trouble with the back and neck. The history as given was that a few months previously she made a change in the underclothing and took cold. This was followed by pain in the neck which prevented her from being about. At that time the slightest motion of the head was extremely painful. No other joints were involved. The arms for some time could not be used freely, the left one being worse. Under general treatment, with fixation of the neck, the patient gradually improved, so that at the present time, except for the rigidity of the upper dorsal and lower half of the cervical spine, she is well.

Case 5.—Hypertrophic arthritis with irritation of the intercostal nerves causing the so-called intercostal neuralgia.

Patient.—Mr. R., was first seen in August, 1900, because of a persistent pain in the left side, a condition which had been present for nearly a year, which had not yielded to drugs or other forms of treatment, and which had been so persistent and interfered so much with the ordinary activities that the patient, who was an active business man, had practically decided to retire from all active life. The back was rounded forward, there was limitation of motion in the lower dorsal and lumbar regions, the motions of the spine increased the pain along the line of the intercostal nerves, and sudden movements, such as coughing or sneezing, increased it markedly. The case was one of hypertrophic arthritis of the dorsal spine with pressure on and irritation of the intercostal nerves.

Treatment.—A jacket was applied holding the body erect and relieving the irritation of the dorsal spine consequent on motion, with immediate relief and with entire recovery in a few months. The patient remained well after that time.

SACROILIAC LESIONS

Undoubtedly the most common joints to show lesions of any sort are those between the ilia and the sacrum, since these joints are supported entirely by muscles and ligaments, and consequently anything which interferes with the tone of those may lead to strain of the joints or sag or displacement of the bones; and since the sacral plexus of nerves passes directly over these joints, it is not to be wondered at that in many of such cases pain is present, due to the irritation of some portion of this plexus. Undoubtedly more of the cases of sciatica are due to this than to any other one thing, and in such cases not only may pain be present, but the continued irritation of the nerve may lead to an exaggeration of the reflexes, or, if the pressure is severe enough, actual paralysis may exist.

The location of such pain naturally varies and depends on the amount of or the portion of the plexus that is irritated. It may be quite general and extend the length of the leg, or it may be confined to definite areas, there being areas of hyperesthesia or anesthesia. The symptoms will be increased by motion in the affected joint, and are almost invariably worse at night or when the body is for long in the recumbent position, during which time the supporting muscles relax. With this relaxation the lumbar spine is allowed to sag and thus drags the upper part of the sacrum backward, producing strain of the joint with resulting pain, either local or referred.

The increase in the pain in sciatica when the patient is in bed and the common custom in such cases of sleeping in a chair in the semierect position is to be explained in this way.

Case 6.—Weakness of the sacroiliac joints following injury and acute illness, with ultimate displacement of the sacrum, this causing obstinate sciatica.

Patient.—Miss S., had been an invalid for fifteen years, suffering much from sciatica, with backache and neuritis of the right arm. The history is that seventeen years previous to her being seen she fell over some stairs, striking the lower part of the back, being quite lame for a short time, with considerable pain referred to the lower back. Two years later she had an acute illness, with a high temperature which lasted for a few days. After this a severe backache developed, with pain in the right leg, and ever since then the patient had pain in the leg, called sciatica, with continued backache, and in practically all of that time was an invalid. The menstrual period was attended with marked increase of pain.

Examination.—The patient was in extremely poor general condition, with extreme tenderness over the region of the sacrum and especially the sacroiliac articulations. She was able to walk only with the use of a cane, and any motion of the lumbar spine or of the thighs which produced motion or strain of the pelvic joints caused an increase of the pain. The straight leg raising, in which the hamstring muscles are made tight, was exceedingly painful and allowed to only a few degrees. There was much pain referred to the arms and hands, increased or relieved by posture. The history suggested weakening of the sacroiliac joints at the time of the injury, with a relaxation of the joints at the time of the acute illness, and the displacement of the sacrum backward at that time, the sciatica representing the irritation of the sacral plexus consequent on the displacement of the bone. The pain of the arm, neuritis, was due to the extreme forward position of the shoulder, a part of the weakened condition, and the crowding of the brachial plexus against the ribs by the head of the humerus.

Treatment and Course of Disease.—The sacroiliac joints were manipulated under an anesthetic, the sacrum was forced into place with a marked temporary increase of the sciatic pain, but with a marked relief almost at once in the general nervous tension. With the aid of supports, consisting first of the adhesive plaster strapping, later on of the pelvic belt and a flexible back brace, the patient was able to get about, and has gradually regained her health, with nearly the normal return of the functions of the body. With the change in the posture and the holding of the shoulder back the pain in the arms has disappeared.

Case 7.—Obstinate sciatica due to displacement of the sacrum.

Patient.—Mr. A., aged 19, midshipman at Annapolis, had been under active treatment and away from his duties for the past ten months because of severe sciatica in the right leg. The trouble came on suddenly and persisted and caused much suffering ever since. In that time the patient had all sorts of treatment, including injections along the nerve sheath, massage, long periods of rest, drugs, etc., with no improvement.

Examination.—The patient stood with the muscles of the spine and thighs all in marked spasm, with the body listed to the left, with forward bending and side bending markedly limited, with the spinal motions much more free when sitting, in which position the hamstring muscles are relaxed, with the hip motions free except the straight leg raising, this being almost entirely limited on the left side, and considerably limited on the right, with marked tenderness over the sacroiliac articulations. The case was one of backward displacement of the sacrum on the left side, with the sciatica resulting from the irritation of the sacral plexus.

Treatment and Course of Disease.—The patient was admitted to the hospital and the joints manipulated, but the replacement of the bone could not be accomplished at that time. Plaster-of-Paris jackets were applied and other forms of spinal support without relief, and three weeks later another manipulation was attempted, this time with a distinct slip of the bone into place, with immediate relief of the sciatica. A few days later the patient left the hospital, and on the way across the city the bone slipped slightly out of place, with an instant return of the sciatic pain, which was at once corrected by the application of a brace which forced the bone back into place. Since then, with the use of a pelvic belt, there has been no further difficulty. There has been no return of the pain.

Case 8.—Severe sciatica due to displacement of the sacrum and with severe brachial neuralgia due to the forward position of the shoulder.

Patient.—Miss W., aged 28, was seen four years ago because of severe sciatica which had been present off and on for four years. In that time the patient had had much backache and the sciatica had been so constant, making sleep difficult, that the patient had become very nervous and was in a marked neurasthenic state.

Treatment and Course of Disease.—From the attitude assumed in standing and the motion allowed, together with the tenderness over the sacroiliac joints, a lesion of these joints was diagnosed and fixation apparatus applied, but entirely without relief. Manipulation was then attempted and resulted in a marked slip of the sacrum into place, with instant relief to the pain, with an immediate ability to go about, with a rapid disappearance of the neurasthenic symptoms, and an entire relief of symptoms ever since. A belt was worn for a few months following the manipulation. The patient also complained much of pain in the arms, chiefly the right, which interfered much with all function and which caused much suffering at night. This persisted after the sciatica was relieved by the manipulation and in an attempt to control it she was at one time confined to bed for three months under the care of most competent physicians, but without relief. Recognizing later that the pain in the arm was due to the crowding of the brachial plexus by the head of the humerus in the forward position and that this forward position was held by adhesions in the coracoid bursa, I manipulated the shoulder so that the adhesions were freed and the erect shoulder position could be maintained. This was followed by distinct relief at once, with a gradual disappearance of the "nerve" pain, until the patient was entirely well. A light shoulder-brace was worn to hold the shoulders back for several months.

THE SHOULDER MALPOSITIONS AND THEIR EFFECT ON THE BRACHIAL PLEXUS

With the drooping of the shoulder forward the scapula rotates so that its axis is directed forward and outward at the top, and with this the glenoid cavity is lowered so that the shoulder is finally supported by the humerus resting against the ribs. In this position, naturally, the axillary structures are compressed between the humerus and the ribs. If the patient is stout, all of the structures are compressed, resulting frequently in disturbances of circulation in the hands and arms as well as pain along the distribution of the branches of the brachial plexus. If the patient is thin the ulnar nerve, which is most posterior, is commonly pressed on and the frequent ulnar neuritis seen in such cases is in this way explained. If, in addition, the costume is so arranged that the fat tissue under the axilla and below the bust is crowded up under the arm, the compression of the axillary structures by the arm is increased.

Occupation or attitude which increases this forward position naturally increases the pain and at times leads to an entire inability to use the hand, seen most strikingly in the so-called "writer's cramp."

Such being the case, naturally the correction of the position of the shoulder so that the axillary structures are no longer compressed and the training of the individual to use the body erect rather than drooping are of the utmost importance for the cure of such conditions. If in such cases the forward flexion of the upper part of the scapula makes it impossible to extend the shoulder fully, as is often the case, an operation for the correction of this should be performed, as until this is corrected real cure can not take place.

Case 9.—Marked stoop shoulder with an extreme degree of brachial neuritis and writer's cramp.

Patient.—A man, aged 30, tall, of slender build, always having stooped considerably, had, for a year previous to the time of the first consultation in July, 1908, suffered much from pain in the right shoulder and arm, always made worse by writing, and being a journalist by profession, this seriously interfered with his occupation. The condition had become so bad that all use of the hand had to be avoided, and the patient had become much broken in health as the result of the constant pain.

Examination.—At the time of the examination the forward position of the shoulder was most evident, and the fact that the brachial neuralgia could be increased by increasing the forward position was demonstrated. As the result of the long-standing forward position of the shoulder, which had undoubtedly occurred during childhood, the scapulæ were flexed forward, so that the erect position of the shoulder was impossible.

Treatment.—Accordingly, after some entirely unsuccessful experimentation with braces, an operation was performed consisting of the removal of the upper part of the scapula, so that the shoulders could then be carried erect; and with this, with the temporary use of braces, the neuralgia and pain in the arm gradually ceased, until at the present time the patient is practically well.

Case 10.—*Patient.*—A young woman, aged 30, a professional violinist, sought relief from pain in the right hand, always brought on in connection with her violin-playing, which had become so marked that the question of giving up her profession had been forced on her. The pain was all referred to the hand, with nothing locally to show for it, and in the examination it was found that the patient within the past year had changed the style of bowing, using the arm more horizontally than previously, and that the pain was developed only when the bow was drawn to its extreme length, in which position the shoulder was carried markedly forward. When the shoulder reached a certain point the pain developed so markedly that it was difficult for the patient to hold the bow.

Treatment.—After some consideration of the problem, a light shoulder brace was applied which prevented this extreme forward position of the shoulder, and with this, and with the training of the patient to use the shoulder rightly, the pain and disability have been entirely controlled. (See also Cases 6 and 8.)

THE EFFECT OF WEAKNESS OF THE PELVIC JOINTS ON THE GAIT IN PARALYTIC CONDITIONS

In nearly all of the paralytic conditions the body is inclined forward in walking, and frequently the knees are used flexed. Not only do both of these positions favor strain of the sacroiliac joints, but neither position can be for long maintained by any one, irrespective of the paralysis, without strain of these joints resulting. If these joints are strained and become relaxed, since the pelvis represents the structural base of the body to which all of the trunk and thigh muscles are attached, obviously locomotion becomes difficult, because these trunk and thigh muscles naturally work at a disadvantage and the gait is peculiar simply because of the joint strain, entirely apart from the paralysis. Recognition of this fact and provision of proper support for the pelvic joints frequently results in marked improvement in the gait and the disability so commonly present in these paralytic conditions can frequently be strikingly modified. The joint protection does not, of course, change or cure the paralysis, but frequently lessens the disability to a marked degree, and should be definitely recognized in the treatment of these conditions.

Case 11.—*Patient.*—Mr. J., aged 41, sought treatment because of trouble with the feet, giving the history that for some months he had been growing increasingly more helpless, having difficulty in keeping his balance, difficulty in walking in the dark, and much unsteadiness on turning quickly, with some drag of the toes. The case was one of locomotor ataxia, with entire absence of the reflexes, disturbed reaction of the pupil, and in connection with this a distinct flat foot, with a well-marked strain of both sacroiliac joints.

Treatment and Course of Disease.—A pair of foot plates were given to relieve the foot strain, the adhesive plaster strapping was applied to the lower back and a pelvic belt ordered to increase the pelvic stability. At the time of the second visit the patient reported himself as being markedly improved and as being able to walk much more freely. The belt was applied and this continued in connection with the foot plates, with continued improvement over the condition which was present at the time of the first visit. The apparatus does not, of course, change in any sense the cord lesion, but by relieving the mechanical strain caused by the weakness of the pelvic joints and the feet, the disability, which is the natural result of his cord lesion, is much less marked and the patient correspondingly elated.

Case 12.—Lateral sclerosis of the spinal cord.

Patient.—Mrs. W., aged 57, had been growing progressively more helpless. The progress has been the natural progress of such a case, with gradually increasing disability. For the past few years there had been an increasing difficulty in the control of the urine. At the time of the examination it was perfectly obvious that in connection with the spinal cord lesion the pelvic joints were markedly strained and as the result of the chronic strain the sacrum was slightly displaced.

Treatment and Course of Disease.—At that time, as several patients with similar joint lesions had been markedly relieved of troublesome frequent micturition in connection with the treatment of the joints, manipulation of the sacroiliac joint was advised in the hope that the difficulty with the micturition would be controlled in her case, and hoping at the same time that the gait could be improved. Following the manipulation there was distinct improvement in the gait, so that the patient, who had previously been unable to walk across the room without assistance and unable to go over the stairs, was able to walk across the room with comparatively little unsteadiness and was able, with the assistance of the bannisters, to go up and down stairs. The character of the gait was curiously changed following the manipulation, and from the usual dragging of the toe seen in such cases the gait at first was more like the gait of the high-stepping horse, the knees being drawn up markedly as the step was taken forward. The patient during the past year has worn a belt about the pelvis and has had various forms of supports to relieve the strain on the sacroiliac joints and in that time has been more active than it was possible for her to be in the few years previous. The case, of course, represents a spinal cord lesion in which the prognosis is presumably hopeless, but with distinct improvement resulting from the relief of the joint strain which is a necessary result of the use of the body with such a paralytic condition.

CIRCULATORY DISTURBANCES IN THE NEURASTHENIC OR IRRITABLE SPINE

In any condition in which the spinal muscles are weakened the body must droop or be inclined forward during use. Not only this, but if the body is used in the forward position for long the muscles become fatigued, and if the use is continued they necessarily are weakened, so that a still further tendency for the spine to droop exists. The posture with the weakened muscles must result in strain of the various spinal ligaments, especially the interspinous, a condition which shows by the painful points along the spine so commonly found in such cases.

The spinal muscles receive their blood supply in the lumbar region from the lumbar arteries and in the dorsal region from the intercostal arteries. Branches are given off from these vessels which go directly into the spinal canal on a level with each vertebra. If for any reason the muscles of the spine are weak so that there is not the usual amount of blood supply to the muscles, it is probable that the flow of blood through these spinal branches is also not normal, and if this is the case it must mean that the spinal cord is less well supplied with blood than normal. It is possible also that the interference with the normal motions of the spine which must result if the muscles are weakened results also in venous and lymphatic stasis, so that a congestion exists which also interferes with the nutrition of the spinal cord.

These are conditions which naturally can not be proved anatomically, and which must be matters of speculation, but as a proposition it seems reasonable, and the marked change in the neurasthenic elements in many of these cases as soon as the spinal strain is relieved so that the free action of the trunk is possible would seem to bear out such a supposition. If such a condition does exist it should emphasize the importance of training our patients in proper poise, not simply because of esthetic considerations, but because by so doing the function of all the organs will be carried on more easily, and especially because the circulation in the spinal cord will be more free and the nerve centers which control the various structures may be better nourished and consequently possess greater vigor.

THE REAL SIGNIFICANCE OF THE KERNIG SIGN

The limitation of the straight leg raising when the patient is lying on the back or when sitting has been used, since it was originally described, as a common test for sciatica and other conditions in which the nerves have been more or less involved. The limitation in this movement is brought about by spasm of the hamstring muscles, and as these muscles, together with the lumbar muscles, are the ones which are concerned in the protection of the sacroiliac joints, it seems probable to me that the "sign," as it is commonly designated, is almost always, if not always, simply an indication of strain or disease in these joints. I have never seen the "sign" present unless other tests were present confirmatory of the joint lesion, and since a large proportion of the cases of sciatica are due to the irritation of the sacral plexus in connection with the lesion of the sacroiliac joint, and since in many of the paralytic conditions the sacroliac joints must be strained, the presence of the sign in these cases is easily explained. It seems probable to me that the "sign" is chiefly of value as indicating joint weakness and possesses little other significance.

Such are a few of the subjects which I feel should be fully understood by both the neurologist and the orthopedic surgeon. Our function is to prevent as well as to control disease, and both of these elements are involved in the problems which, because of the small amount of time available, have been so briefly presented.

If we can train our patients to use their bodies rightly not only will there be less waste of both nervous and physical force, but the suffering which at times comes because of the faulty use will not occur. If the conditions here decribed are recognized, the relief of the suffering as well as the control of the disease become matters of much greater certainty than they have been in the past.

In approaching our patients not only should we consider the pathology concerned in their troubles, but also we should endeavor to understand fully the anatomic relations of the parts and the possible effect of imperfect mechanical adjustment.

372 Marlboro Street.

ABSTRACT OF DISCUSSION

Dr. T. Diller, Pittsburg, Pa.: I was entirely ignorant of the disease of the sacroiliac joints until my attention was directed to them by Dr. David Silver, an orthopedic surgeon, two years ago. Since then I have been able to recognize three of these cases, and I am sure they would have been obscure to me without the assistance he gave me. In one case, a woman presented many neurasthenic signs, such as pain along the spine, and there was a certain pain which was different from anything I had noted. She stated that the pain came in the neighborhood of the sacrum about the buttocks very suddenly at night when she would turn in bed. It was not the sort of pain that one encounters in the neurasthenic. Dr. Silver demonstrated distinct looseness in the sacroiliac joint, applied a proper bandage, and the patient was relieved. A medicolegal case I saw recently was another of this sort. The patient was a young woman of about 25 who was riding in a railway train on a so-called reclining chair, riding at night with her feet up on the chair in front of her. The train came into a collision, and she was so seated that she was doubled up like a jack knife, her feet being brought in contact with her head, so that there was a very forced doubling of the joint at the hips. Now, this patient complained of a number of neurasthenic symptoms: great pain about the region of the sacrum and running down the back of the thigh, as Dr. Goldthwait has mentioned. There was not the ordinary spinal tenderness that we so frequently meet in these cases, and a careful examination of this patient was made with the assistance of Dr. Silver; he demonstrated looseness of this joint by having the patient raise her thigh and put it down while she was in a standing position, and we could distinctly feel crepitus. My experience is limited in this field, yet this is a very important matter, and I am now on the lookout for these cases of sacroiliac disease. I have seen a number of cases of stiffness of the spine, and they are quite obvious if one is on the lookout for them, and I think the only chance of missing them is by not thinking of this condition.

Dr. Robert L. Pitfield, Germantown, Philadelphia: I recall two cases of sacroiliac disease following labor, one of which yielded to strapping of the back, but I was compelled in another case to apply a belt and bind the woman, and she suffers even now from pain, particularly on rising from bed in the morning.

Dr. William A. Jones, Minneapolis: In many of these cases that Dr. Goldthwait has described, in which there is actual nerve irritation, is it due to changes in position of the vertebra, and is it probable or likely that aside from the sacroiliac joint that the position of the other vertebræ can be changed at all? This, I think, is a difficult question for neurologists to appreciate fully.

Dr. J. E. Goldthwait, Boston: I do not believe that the vertebræ change their position very much. The cervical vertebræ, I am sure, can be slipped a little bit out of place, and I am inclined to think that is more common than we generally suppose. I do not believe that the dorsal and lumbar vertebræ change their places much unless there is severe trauma. I think that the last lumbar vertebra can be slipped forward on the sacrum much more commonly than is generally supposed. Pregnancy is the most common source of the relaxation of the joint, but that is rarely productive of pain such as a neurologist would note, because the relaxation is so soft and the tissues are all so much relaxed that the nerves and all the tissues are stretched, and there is comparatively little pressure. If the pain continues and the stability does not return with the use of a belt or proper support, I should suspect that the bones were not in quite the original position, because usually when they are in the normal position Nature is ready with the muscles and ligaments to hold them in that position.

In so-called cases of railroad spine, examine the sacroiliac joint. I never saw a railroad spine which was not really a sacroiliac joint sprain. If you will read the books on this condition you will find that the profession is not in accord as to what it is, and if you will study the mechanics of the spine and the nature of the accidents commonly productive of railroad spine, the wonder is not that people have the sacroiliac joint strains which lead to the weak backs and nervous backs, etc., but that they all do not get it. It is the sudden stopping and the jerking of the body forward or backward, with the muscles off their guard, that causes the trouble.

THE SURGICAL ASPECTS OF CEREBRAL DECOMPRESSION

WITH REMARKS ON THE ETIOLOGY AND CERTAIN MANIFESTATIONS OF PAPILLEDEMA *

CHARLES H. FRAZIER, M.D.
Professor of Clinical Surgery, University of Pennsylvania; Surgeon to the University Hospital
PHILADELPHIA

Though having had the privilege of presenting a paper on a kindred subject to this Section but a year ago, your Secretary has been kind enough to invite me to participate in your transactions again and has assigned to me the topic of the "Surgical Aspects of Cerebral Decompression." Rather than to any contribution of my own, I attribute this opportunity chiefly to the fact that one of your members, Dr. de Schweinitz, has been so closely identified with all the neurologic cases in my clinic, and in this connection I should like to emphasize the importance not only from the standpoint of the patient's welfare, but as a means of accurate and reliable observation of the closest coöperation, between the ophthalmic and neurologic staff on the one hand and the surgical on the other. An exhaustive study of the case before operation at the hands of the experienced neurologist and ophthalmologist, their observations of the lesion at the time of the operation, and their continued studies of the after-effects serve as a safeguard against surgical blunders and guarantee accuracy and reliability in the published records.

Of all the phases of papilledema, none has aroused more interest and discussion than the etiology. The conditions in which it has been associated are well known, notably tumor, hydrocephalus, and more recently traumatic lesions. It has been assumed by some that the most important factor in its pathogenesis is increased intracranial tension. Plausible as this theory is, it is not borne out by experimental evidence, at least with one or possibly two exceptions experimenters have thus far failed to produce a papilledema solely by increasing intracranial tension. Because of the existing obscurity as to its etiology, I have with the collaboration of Drs. de Schweinitz, Sweet, Prime and Holloway, made a series of observations in the Laboratory of Experimental Surgery of the University of Pennsylvania, for the purpose of determining for ourselves whether increased tension did or did not play any part. The experiments will be published in detail together with others bearing on the subject of decompression so that I shall allude here only to the essential features.

Two methods of increasing intracranial tension were employed, the wet and the dry. By the dry method, a small rubber bag was introduced beneath the skull after splitting the dura and retained in place by a special appliance. By elevating the reservoir, the bag was distended with water to the point of maximum tolerance. By the wet method, normal saline solution was introduced through a small canula screwed into the skull; the dura was opened and the rate of flow was regulated by elevating or lowering the reservoir. In some cases, the fluid was introduced into the pretentorial space, in some into the subtentorial space. The degree of intracranial tension was determined by kymographic tracings of the blood pressure, the respiration and in some instances of the brain pressure. Examination of the eyegrounds were made by Dr. de Schweinitz or by Dr. Holloway, before the experiment was begun and afterward at intervals of every few minutes. The degree of intracranial tension was recognized by the increase in blood pressure and by the partial or complete arrest of the respiratory function. In every experiment, tension was increased up to a point where the respiratory function was arrested and it became necessary to resort to artificial respiration to resuscitate the animal.

The following is the summary of the observations:

Case 1.—Summary: Dry method. Extreme degree intracranial tension; no evidence of choked disc; slight dilation and pulsation of nasal branch of retinal veins. The changes in the vessels were quite as marked on the opposite side as on that on which pressure was inserted.

Case 2.—Summary: Dry method. Under a degree of intracranial tension, sufficient to cause arrest of respiratory function and elevation of the blood pressure, signs of intracranial tension continued from one to two hours. There were no changes in the eyeground other than filling and subsequently pulsation of the retinal veins.

Case 3.—Summary: Dry method. Increase of intracranial pressure attended with most profound disturbance of the respiratory and circulatory centers caused practically no changes whatsoever in the eyeground, not even the filling and pulsating of veins as observed in previous experiments.

---

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

CASE 4.—Summary: Wet method. Intracranial pressure increased by introduction of 185 c.c. of normal saline solution in subtentorial region. Much smaller quantity required to cause changes in retinal vessels and the death of the animal than in pretentorial region. No signs of papilledema.

CASE 5.—Summary: Wet method. The enormous amount of saline solution (2,520 c.c.) which was absorbed in so short a time (two hours) in itself was remarkable. The eye symptoms, except exophthalmus, were not particularly marked; no edema or pulsation having occurred. At the autopsy all the organs, with the exception of the lungs, were filled with fluid.

CASE 6.—Summary: Dry method. Increase of intracranial pressure (by distention of a bag inserted within the cranium) up to and beyond the physiologic limit, as indicated by the arrest of the respiratory and circulatory function, failed to provoke papilledema. At times the discs were bleached; at times the veins were distended, and at times there was pulsation of the vessels, but nothing more.

CASE 7.—Summary: Wet and dry method combined. The intracranial pressure was increased with the distended bag until there were signs of intracranial tension; the latter was increased up to and beyond the maximum degree of toleration by the introduction of 100 c.c. of normal saline salt solution. No changes in the eyegrounds were observed.

From the experiments these conclusions are drawn:

1. Increase of intracranial tension by artificial means up to a point attended with profound disturbance of the circulatory and respiratory functions was in no instance attended with development of a papilledema, except in two instances not here recorded, and in these there was no marked swelling of the disc, but only a slight edema and filling in of the center of the discs.
2. The duration of the observation varied from two to ten hours; in one instance increased intracranial tension was maintained and observations made from six o'clock in the evening to four o'clock the next morning. So that the element of time did not affect the results.
3. In some instances the eyegrounds were bleached (the stage of anemia) and in many there was more or less fulness and occasionally pulsation of the retinal veins, but nothing else.
4. The degree of intracranial tension artificially produced in these experiments exceeded by far that which obtains in the vast majority of these lesions of which papilledema is a clinical manifestation.
5. Therefore, in the etiology of papilledema some factor or factors other than increased intracranial tension play an important part.
6. What these may be is still a matter of conjecture.

Papilledema and its relation to intracranial trauma is a subject which has commanded our attention for a number of years. The statement has been made that papilledema is a more or less constant accompaniment of those cases of intracranial trauma in which there is obstruction to the venous circulation, the stage of *Stauungs hyperemie* which, according to Kocher's scheme, is the first stage of cerebral compression. These include cases of cerebral contusion, in which edema is a conspicuous feature, although it might include also cases of large intracranial hemorrhages. For the past two years Dr. de Schweinitz has examined almost all the cases of this description in my service at the University Hospital, and in all he has discovered but two cases of papilledema. This is an insignificant number on which to base any conclusion, but a small number of carefully studied and observed cases is often of greater value than a mass of imperfectly digested material.

Because of their direct bearing not only on the etiology of papilledema but on the question of operative interference for relief, I refer to the cases in some detail.

CASE 1.—A young man, aged 25, sustained an injury to his head in falling from a trolley car.[1] There was no positive evidence of fracture of the skull and the case was regarded as one of cerebral contusion. The principal symptoms were vomiting, delirium and frontal headache. The latter was intense and persisted in this intense form for at least ten days after the accident. The pupils were equally dilated and there were no focal symptoms. The superficial veins of the scalp were conspicuously dilated.

January 10 (seventh day): Dr. de Schweinitz examined the eyes with the following result: The right disc edematous; + 3.5 D.; veins enormously distended; retinal hemorrhage below disc; left disc + 5 D.; veins distended and hemorrhages above and below disc.

January 13 (tenth day): Swelling of discs not so marked between 3 and 4 D. Veins not so full. Vision O. D. 4/5 O. S. 4/6.

January 19 (sixteenth day): R. O. highest surface of disc + 4 D.; some hemorrhage L. O. disc + 4 O.; hemorrhage above; veins very full.

The patient was discharged from the hospital but returned to the out-patient clinic for further observation. Within a few weeks the vision was entirely normal and the papilledema had entirely disappeared.

In this case we see a type of intracranial trauma which would be regarded as a concussion or, more properly, a contusion without evidence of fracture but with symptoms persisting for almost two weeks, at no time attended with unconsciousness, stupor or convulsions, but with a moderately high grade papilledema which subsided spontaneously, that is, without operative intervention. The question of a decompressive operation was considered, but because of the absence of conditions that could be said to be alarming, was not resorted to.

CASE 2.—A woman, aged 35 years[2] fell from a trolley car and sustained a serious injury to her head. On admission she was completely unconscious and did not respond to any external stimuli. There was a large hematoma on the left occipitotemporal region, but no fracture could be felt. There was no bleeding from the nose, mouth or ears; the pulse was slow and intermittent and the blood pressure 128 millimeters of mercury. Examination of the urine discovered 3.5 per cent. of sugar. There were no sensory and no motor phenomena except in the muscles supplied by some of the cranial nerves. There was some weakness of the muscles supplied by the left facial nerve. In examining the eye, Dr. de Schweinitz reported as follows: R. O. oculomotor palsy; superior, inferior and internal rectus involved; ptosis not quite complete; pupils dilated about five millimeters; no reaction to light; well marked edema of the disc + 3 D.; enormous dilation of the retinal veins and moderate tortuosity; arteries unchanged; L. O. no involvement of the external ocular muscles; condition of the disc and retinal veins same as on the other side. The symptoms were attributed to a serious cerebral contusion and the involvement of the cranial nerves to small nasal hemorrhages, possibly to a fracture of the petrous bone.

January 10 (seventh day): All the edges of the discs were clear except the nasal; the veins were distinctly smaller; right eye still diverges.

January 20 (seventeenth day): The edges of both discs were perfectly clear and the veins not far from normal in size.

The patient gradually recovered consciousness and from the subsequent mental confusion, and as her life was at no time threatened operative interference was not contemplated.

Whatever other indications there may be for decompression in cases of intracranial trauma, it would appear from these at least that papilledema alone can not be regarded as one. In both instances the papilledema measuring + 7 and + 3.5 diopters respectively sub-

and they are quite obvious if one is on the lookout for them, and I think the only chance of missing them is by not thinking of this condition.

Dr. Robert L. Pitfield, Germantown, Philadelphia: I recall two cases of sacroiliac disease following labor, one of which yielded to strapping of the back, but I was compelled in another case to apply a belt and bind the woman, and she suffers even now from pain, particularly on rising from bed in the morning.

Dr. William A. Jones, Minneapolis: In many of these cases that Dr. Goldthwait has described, in which there is actual nerve irritation, is it due to changes in position of the vertebra, and is it probable or likely that aside from the sacroiliac joint that the position of the other vertebræ can be changed at all? This, I think, is a difficult question for neurologists to appreciate fully.

Dr. J. E. Goldthwait, Boston: I do not believe that the vertebræ change their position very much. The cervical vertebræ, I am sure, can be slipped a little bit out of place, and I am inclined to think that is more common than we generally suppose. I do not believe that the dorsal and lumbar vertebræ change their places much unless there is severe trauma. I think that the last lumbar vertebra can be slipped forward on the sacrum much more commonly than is generally supposed. Pregnancy is the most common source of the relaxation of the joint, but that is rarely productive of pain such as a neurologist would note, because the relaxation is so soft and the tissues are all so much relaxed that the nerves and all the tissues are stretched, and there is comparatively little pressure. If the pain continues and the stability does not return with the use of a belt or proper support, I should suspect that the bones were not in quite the original position, because usually when they are in the normal position Nature is ready with the muscles and ligaments to hold them in that position.

In so-called cases of railroad spine, examine the sacroiliac joint. I never saw a railroad spine which was not really a sacroiliac joint sprain. If you will read the books on this condition you will find that the profession is not in accord as to what it is, and if you will study the mechanics of the spine and the nature of the accidents commonly productive of railroad spine, the wonder is not that people have the sacroiliac joint strains which lead to the weak backs and nervous backs, etc., but that they all do not get it. It is the sudden stopping and the jerking of the body forward or backward, with the muscles off their guard, that causes the trouble.

THE SURGICAL ASPECTS OF CEREBRAL DECOMPRESSION

WITH REMARKS ON THE ETIOLOGY AND CERTAIN MANIFESTATIONS OF PAPILLEDEMA *

CHARLES H. FRAZIER, M.D.
Professor of Clinical Surgery, University of Pennsylvania; Surgeon to the University Hospital
PHILADELPHIA

Though having had the privilege of presenting a paper on a kindred subject to this Section but a year ago, your Secretary has been kind enough to invite me to participate in your transactions again and has assigned to me the topic of the "Surgical Aspects of Cerebral Decompression." Rather than to any contribution of my own, I attribute this opportunity chiefly to the fact that one of your members, Dr. de Schweinitz, has been so closely identified with all the neurologic cases in my clinic, and in this connection I should like to emphasize the importance not only from the standpoint of the patient's welfare, but as a means of accurate and reliable observation of the closest coöperation, between the ophthalmic and neurologic staff on the one hand and the surgical on the other. An exhaustive study of the case before operation at the hands of the experienced neurologist and [illegible] eir observations of the lesion at the ti[illegible], and their continued studies of the after-effects serve as a safeguard against surgical blunders and guarantee accuracy and reliability in the published records.

Of all the phases of papilledema, none has aroused more interest and discussion than the etiology. The conditions in which it has been associated are well known, notably tumor, hydrocephalus, and more recently traumatic lesions. It has been assumed by some that the most important factor in its pathogenesis is increased intracranial tension. Plausible as this theory is, it is not borne out by experimental evidence, at least with one or possibly two exceptions experimenters have thus far failed to produce a papilledema solely by increasing intracranial tension. Because of the existing obscurity as to its etiology, I have with the collaboration of Drs. de Schweinitz, Sweet, Prime and Holloway, made a series of observations in the Laboratory of Experimental Surgery of the University of Pennsylvania, for the purpose of determining for ourselves whether increased tension did or did not play any part. The experiments will be published in detail together with others bearing on the subject of decompression so that I shall allude here only to the essential features.

Two methods of increasing intracranial tension were employed, the wet and the dry. By the dry method, a small rubber bag was introduced beneath the skull after splitting the dura and retained in place by a special appliance. By elevating the reservoir, the bag was distended with water to the point of maximum tolerance. By the wet method, normal saline solution was introduced through a small canula screwed into the skull; the dura was opened and the rate of flow was regulated by elevating or lowering the reservoir. In some cases, the fluid was introduced into the pretentorial space, in some into the subtentorial space. The degree of intracranial tension was determined by kymographic tracings of the blood pressure, the respiration and in some instances of the brain pressure. Examination of the eyegrounds were made by Dr. de Schweinitz or by Dr. Holloway, before the experiment was begun and afterward at intervals of every few minutes. The degree of intracranial tension was recognized by the increase in blood pressure and by the partial or complete arrest of the respiratory function. In every experiment, tension was increased up to a point where the respiratory function was arrested and it became necessary to resort to artificial respiration to resuscitate the animal.

The following is the summary of the observations:

Case 1.—Summary: Dry method. Extreme degree intracranial tension; no evidence of choked disc; slight dilation and pulsation of nasal branch of retinal veins. The changes in the vessels were quite as marked on the opposite side as on that on which pressure was inserted.

Case 2.—Summary: Dry method. Under a degree of intracranial tension, sufficient to cause arrest of respiratory function and elevation of the blood pressure, signs of intracranial tension continued from one to two hours. There were no changes in the eyeground other than filling and subsequently pulsation of the retinal veins.

Case 3.—Summary: Dry method. Increase of intracranial pressure attended with most profound disturbance of the respiratory and circulatory centers caused practically no changes whatsoever in the eyeground, not even the filling and pulsating of veins as observed in previous experiments.

---

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Case 4.—Summary: Wet method. Intracranial pressure increased by introduction of 185 c.c. of normal saline solution in subtentorial region. Much smaller quantity required to cause changes in retinal vessels and the death of the animal than in pretentorial region. No signs of papilledema.

Case 5.—Summary: Wet method. The enormous amount of saline solution (2,520 c.c.) which was absorbed in so short a time (two hours) in itself was remarkable. The eye symptoms, except exophthalmus, were not particularly marked; no edema or pulsation having occurred. At the autopsy all the organs, with the exception of the lungs, were filled with fluid.

Case 6.—Summary: Dry method. Increase of intracranial pressure (by distention of a bag inserted within the cranium) up to and beyond the physiologic limit, as indicated by the arrest of the respiratory and circulatory function, failed to provoke papilledema. At times the discs were bleached; at times the veins were distended, and at times there was pulsation of the vessels, but nothing more.

Case 7.—Summary: Wet and dry method combined. The intracranial pressure was increased with the distended bag until there were signs of intracranial tension; the latter was increased up to and beyond the maximum degree of toleration by the introduction of 100 c.c. of normal saline salt solution. No changes in the eyegrounds were observed.

From the experiments these conclusions are drawn:

1. Increase of intracranial tension by artificial means up to a point attended with profound disturbance of the circulatory and respiratory functions was in no instance attended with development of a papilledema, except in two instances not here recorded, and in these there was no marked swelling of the disc, but only a slight edema and filling in of the center of the discs.

2. The duration of the observation varied from two to ten hours; in one instance increased intracranial tension was maintained and observations made from six o'clock in the evening to four o'clock the next morning. So that the element of time did not affect the results.

3. In some instances the eyegrounds were bleached (the stage of anemia) and in many there was more or less fulness and occasionally pulsation of the retinal veins, but nothing else.

4. The degree of intracranial tension artificially produced in these experiments exceeded by far that which obtains in the vast majority of these lesions of which papilledema is a clinical manifestation.

5. Therefore, in the etiology of papilledema some factor or factors other than increased intracranial tension play an important part.

6. What these may be is still a matter of conjecture.

Papilledema and its relation to intracranial trauma is a subject which has commanded our attention for a number of years. The statement has been made that papilledema is a more or less constant accompaniment of those cases of intracranial trauma in which there is obstruction to the venous circulation, the stage of *Stauungs hyperemie* which, according to Kocher's scheme, is the first stage of cerebral compression. These include cases of cerebral contusion, in which edema is a conspicuous feature, although it might include also cases of large intracranial hemorrhages. For the past two years Dr. de Schweinitz has examined almost all the cases of this description in my service at the University Hospital, and in all he has discovered but two cases of papilledema. This is an insignificant number on which to base any conclusion, but a small number of carefully studied and observed cases is often of greater value than a mass of imperfectly digested material.

Because of their direct bearing not only on the etiology of papilledema but on the question of operative interference for relief, I refer to the cases in some detail.

Case 1.—A young man, aged 25, sustained an injury to his head in falling from a trolley car.[1] There was no positive evidence of fracture of the skull and the case was regarded as one of cerebral contusion. The principal symptoms were vomiting, delirium and frontal headache. The latter was intense and persisted in this intense form for at least ten days after the accident. The pupils were equally dilated and there were no focal symptoms. The superficial veins of the scalp were conspicuously dilated.

January 10 (seventh day): Dr. de Schweinitz examined the eyes with the following result: The right disc edematous; + 3.5 D.; veins enormously distended; retinal hemorrhage below disc; left disc + 5 D.; veins distended and hemorrhages above and below disc.

January 13 (tenth day): Swelling of discs not so marked between 3 and 4 D. Veins not so full. Vision O. D. 4/5 O. S. 4/6.

January 19 (sixteenth day): R. O. highest surface of disc + 4 D.; some hemorrhage L. O. disc + 4 O.; hemorrhage above; veins very full.

The patient was discharged from the hospital but returned to the out-patient clinic for further observation. Within a few weeks the vision was entirely normal and the papilledema had entirely disappeared.

In this case we see a type of intracranial trauma which would be regarded as a concussion or, more properly, a contusion without evidence of fracture but with symptoms persisting for almost two weeks, at no time attended with unconsciousness, stupor or convulsions, but with a moderately high grade papilledema which subsided spontaneously, that is, without operative intervention. The question of a decompressive operation was considered, but because of the absence of conditions that could be said to be alarming, was not resorted to.

Case 2.—A woman, aged 35 years[2] fell from a trolley car and sustained a serious injury to her head. On admission she was completely unconscious and did not respond to any external stimuli. There was a large hematoma on the left occipitotemporal region, but no fracture could be felt. There was no bleeding from the nose, mouth or ears; the pulse was slow and intermittent and the blood pressure 128 millimeters of mercury. Examination of the urine discovered 3.5 per cent. of sugar. There were no sensory and no motor phenomena except in the muscles supplied by some of the cranial nerves. There was some weakness of the muscles supplied by the left facial nerve. In examining the eye, Dr. de Schweinitz reported as follows: R. O. oculomotor palsy; superior, inferior and internal rectus involved; ptosis not quite complete; pupils dilated about five millimeters; no reaction to light; well marked edema of the disc + 3 D.; enormous dilation of the retinal veins and moderate tortuosity; arteries unchanged; L. O. no involvement of the external ocular muscles; condition of the disc and retinal veins same as on the other side. The symptoms were attributed to a serious cerebral contusion and the involvement of the cranial nerves to small nasal hemorrhages, possibly to a fracture of the petrous bone.

January 10 (seventh day): All the edges of the discs were clear except the nasal; the veins were distinctly smaller; right eye still diverges.

January 20 (seventeenth day): The edges of both discs were perfectly clear and the veins not far from normal in size.

The patient gradually recovered consciousness and from the subsequent mental confusion, and as her life was at no time threatened operative interference was not contemplated.

Whatever other indications there may be for decompression in cases of intracranial trauma, it would appear from these at least that papilledema alone can not be regarded as one. In both instances the papilledema measuring + 7 and + 3.5 diopters respectively subsided spontaneously within a comparatively short time after the accident, *i. e.*, between two or three weeks.

---

[1] Index File No. 4259. For the report of this case I am indebted to Dr. Edward Martin.

[2] M. B. Index File 4362.

Furthermore, I wish to call attention to the relative infrequency of papilledema as a manifestation of serious types of intracranial trauma. That it may exist in certain instances there is no doubt, but its comparative infrequency, minimizes its significance as a diagnostic sign and as a means of determining the degree of intracranial tension and the necessity of relieving it by surgical measures.

The question of the relation of the papilledema to the size, situation, duration and nature of the tumor is not a new one. That the size of the tumor has little to do with the degree of elevation of the disc is the consensus of opinion; that a cortical or a basal tumor is more apt to cause papilledema than a subcortical, in the white substance of the brain, is also well known, and finally that tumors in the subtentorial region lead to papilledema earlier in the course of the case than pretentorial cases, will not be questioned. In tabulating a series of 19 cases, selected only from patients examined by de Schweinitz and subsequently operated on by myself, I found that with two exceptions (in which the discs measured + 7 and + 9 diopters respectively) whenever a papilledema was present the measurements were rather uniform; that is to say, the majority measured from + 3.5 to + 4 or + 4.5 D. Irrespective of duration, of the nature of the tumor, whether infiltrating or more or less encapsulated, with the size varying from that of a chestnut to a hen's egg, there was a comparatively uniform elevation of + 3 to + 4 diopters. In other words, a trivial and insignificant variation.

TABLE 1

No.	Name.	File No.	Diagnosis.	Operation.	Eye Examination Before Operation.	Eye Examination After Operation.	Result.

If I may be permitted to refer to another threadworn subject, namely, the equality or inequality of the discs in the affected as compared with the unaffected side, I would like to place in evidence a series of cases in which the discs were examined by Dr. de Schweinitz before the operation and we were able at the operation to expose the tumor. In these there was not enough difference between the disc of the affected and that of the unaffected side to enable us to draw any conclusions as to the seat of the tumor. This testimony is in absolute disaccord with the very positive statements of Horsley, whose operative experience has been so exceptionally large, but it agrees with the more recent observations of Mr. Paton. I present this series, small as it is, for what it may be worth, and I may add, I think, without contradiction of Drs. de Schweinitz, Mills, or Spiller, who have examined practically every patient operated on in my clinic, that in cases in which there was any doubt as to whether the lesion was on one side or the other, it was the exception rather than the rule to be able by examining the swelling of the discs alone to draw any definite conclusions. Much help, however, can be obtained by studying the age of the nerve-head changes, that is, which disc has been longest affected, by finding the signs of beginning atrophy, etc., points which Horsley also considers most important.

In dwelling on these various aspects of papilledema I have wandered somewhat afield from the subject assigned me, namely, "The Surgical Aspects of Cerebral Decompression." Reference has already been made to the propriety of decompressing in cases of intracranial trauma with papilledema. Apart from trauma, decompression is practiced as a means of relief in certain cases of hydrocephalus, tumors and internal hydrocephalus, but as there are no ocular manifestations of importance in epilepsy I shall confine my remarks chiefly to tumors with or without hydrocephalus.

It is a well-known fact that the large majority of tumors, whether pretentorial or subtentorial, are inoperable. That is to say, the majority are either inaccessible or impossible of localization, or of such a nature as to make their removal inconsistent with the maintenance of life. To express the percentage of operable tumors in figures is not an easy matter; to estimate it from the results of postmortem observations is obviously misleading; to say that from 75 to 80 per cent. are inoperable is by no means a conservative estimate.

In the surgery of brain tumors there are but two propositions to consider: the radical operation, implying the removal of the tumor, and the palliative operation, cerebral decompression. From what has been said of the operability of brain tumors it will be seen at a glance that in the majority of instances the most we can offer is palliation. But in the case of brain tumor palliation implies much more than it does when applied to other incurable lesions. That is to say, given a patient with an inoperable brain tumor palliation means restoration or preservation of vision, relief from headache and from persistent vomiting, three symptoms which together combine to make the patient's life utterly wretched and unbearable. Without them she or he may continue to live for years in comparative comfort.

Decompression is a very much less formidable procedure , it can be performed in a much shorter time and with but trifling risk to life. It implies the removal of an area of bone with a diameter of from 3 to 5 cm. from the temporal region or occipital region on one or both sides and a free opening in the dura or the removal of a portion of it. Whether or not to decompress in the temporal region will depend to a great extent on the situation of the lesion. In all pretentorial tumors temporal decompression is the operation of choice and in all subtentorial lesions a suboccipital decompression is indicated. Usually, sufficient relief from intracranial tension will be afforded by a unilateral operation; should the tumor grow rapidly and the symptoms recur the operation may be repeated on the opposite side.

For the purpose of studying the effects of decompression on a papilledema when performed in the temporal and suboccipital regions I have tabulated two series of cases (See Tables 2 and 3) from Dr. de Schweinitz's records. Although the disc examination was not made at the same interval after operation in all cases, it would seem that the results of temporal decompression were about as good as these of suboccipital decompression or *vice versa*. While I have never decompressed in the temporal region for lesions of the cerebellum, it is reasonable to assume that by this method we might not obtain the necessary relief of tension for lesions beneath or behind the tentorium. In the case of tumors the cerebellar hemispheres are usually under much greater tension than the cerebral hemispheres, often so great that nothing but the removal of bone from directly over the seat of the hemisphere would afford adequate relief.

Cerebral decompression is called for, as a rule, in inoperable tumors; it may be resorted to, however, as a matter of temporary expediency, when the conditions do not admit of delay and the tumor can not be localized. Delay is inadmissible when the papilledema has persisted from six weeks to two months, whether or not there has been temporary improvement under the influence of mercury or the iodides, when procrastination will lead inevitably to optic atrophy and to blindness.

There should be no question about the advisability of operating in these comparatively early cases if only to save vision. The propriety of operating in the advanced cases, when the patient is already in deep stupor, may be questioned. Bruns, for example, opposes such a course. It should be borne in mind that with the patient unconscious the operation can be performed, as I have had occasion to do, without an anesthetic. The operation can be completed in twenty minutes and, while adding but little to the gravity of the situation, may save the patient's life. A striking example of this was brought to my attention in a patient referred to me by

TABLE 2

Dr. Mills. The case seemed hopeless—the patient was unconscious when brought to the hospital and her life was despaired of. A rapidly executed decompression was followed by subsidence of some of the symptoms with recovery of consciousness. On the other hand, in a similar patient recently operated on for Dr. William G. Spiller, the operation seemed to have no effect on the fatal tendencies.

Finally, a few words as to the immediate and ultimate effects of decompression. At the site of the operation there developes a hernia protruding more or less according to the degree of intracranial tension. This is usually well covered with hair and therefore particularly in women, is not very conspicuous.

The mortality following operations on patients with cerebral or cerebellar tumors will depend on the condition of the patient and the seat of the lesions. The longer the duration of the lesion and the nearer the growth to the pons and medulla the greater the danger. All told, in the past seven years I have had only two fatalities following temporal decompression for cerebral tumors. In one of these the patient was stuperous when operated on, and at the autopsy a large tumor was found extending from the temporal lobe back to and including the pons. In the other the tumor also involved the pons. Of the suboccipital decompressions for tumors or suspected tumors of the posterior fossa in the same period there have been five fatalities, one in each of the years from 1904 to 1908. But three of these cases were operative deaths in the strict sense; that is, the patient never fully recovered from the shock of the operation. The two remaining lingered several weeks.

Vomiting and headache, one or the other or both, are relieved in about two out of every three cases by decompression.

In a word, the effects of decompression are in the main beneficial; in fact, so beneficial that we should not question the propriety of operating even though the case may at first seem hopeless. The only grave and fortunately a very rare consequence is sudden blindness. This has never occurred in our service, and apart from this I have never seen any aggravation of the condition of more than a transitory character.

The expectancy of life is a matter of no little interest; even though the patient survives the ordeal but a year, it is not a little in this period to have saved sight, allayed vomiting and relieved headache. In exceptional instances a longer lease on life may be anticipated. Among my patients is one operated on in 1902, one in 1903 and two in 1904. The larger the tumor and the nearer its approach to the vital centers the shorter will be the period of survival.

ABSTRACT OF DISCUSSION *

DR. JAMES BORDLEY, JR., Baltimore: I believe that I can best emphasize the importance of this subject by relating some statistics gathered from the records of 91 out of nearly 300 of the patients operated on by Dr. Cushing at the Johns Hopkins Hospital.

In determining which eye was the more affected—the one contralateral or homolateral to the tumor—we considered not only the swelling but the actual condition of the nerve head, outside of the swelling, the visual fields and the acuity of vision. This was necessary because while the swelling of one disc is increasing the other may have undergone atrophy and the swelling have entirely disappeared. The eye homolateral to the tumor exhibited the greatest change in 68 per cent. of the patients in whom the location of the tumor was a matter of certainty; the eye contralateral to the tumor in 26 per cent.; and in 6 per cent. swelling was equal on two sides.

There was no relationship between the histology of the tumor and the height of the choked discs, that is, none that could be of assistance in determining from the disc whether we were dealing with a malignant or benign growth. Patients with benign tumors and choked discs or from 1 to 7 D.; those with malignant tumors from 1 to 9 D. The disc in cerebellar cases had an average height of 5½ D.; with tumors situated further forward, 3½ D. There was, however, such a radical difference in the height of swelling of the discs in patients with tumors in identically the same situation that we look upon the degree of swelling as only suggestive but not conclusive as a localizing sign. The height of the swelling in the 182 discs of these 91 patients, before operation, was from 1 to 2 D. in 28; from 2 to 4 in 68; from 4 to 6 D. in 51; from 6 to 9 D. in 25, and in 18 there was complete secondary atrophy; 7 had normal discs.

The average length of time for an appreciable change in the swelling to make its appearance after the operation was two days. The average length of time for the swelling to disappear entirely was six weeks. These periods bore no fixed relation to the height of the swelling, but as a rule, the higher the swelling the slower its recession. In one case with the swelling 6 D. a slight edema was to be found eight months after operation. In two cases with swelling of less than 2 D. there was not a trace to be found forty-eight hours after operation. As a rule the edema of nerves in which atrophy was marked disappeared more rapidly than in those without. The swelling in four eyes of two patients was only lessened but not cleared up by operation. These two patients had large malignant growths and high tension was soon re-established.

The ultimate damage to vision was much greater in those cases in which large exudative masses and definite proliferative changes in the cup, on the surface of the disc and in perivascular lymph spaces, could be detected before operation.

Fifty-nine eyes showed increased vision subsequent to operation; in 65 the vision remained the same and in 16 vision continued to fail. Of the 65 in whom the vision remained the same, 29 had normal vision, 24 were blind, and 12 had vision varying from 20/30 to light perception. Fourteen eyes with normal vision subsequent to operation were not tested before; 2 eyes blind subsequent to were not tested before; 18 eyes tested before but not after operation.

Of those operated on and benefited, 2 without light perception regained it; 2 able to count fingers at six inches recovered vision of 20/40 and 20/20, respectively; 14 with vision of 20/200 or slightly less, the improvement varied from only a nominal gain to perfect sight. Of those showing a loss in vision subsequent to operation, 6 became blind; of this number only 2 had useful vision prior to operation. The cause of the change in these cases was, we think, quite clear, pressure on the tracts and shrinkage of the new connective tissue formation of the disc. In these cases, we feel confident, the ultimate result would have been the same whether they were operated on or not. Eight eyes in patients refusing operation subsequently became blind. Partial or total atrophy of the optic nerve was noted on admission in 52 out of the total of 182 eyes. To review briefly: Of 130 eyes in which the record before and after operation could be compared, 59 had increased vision, 16 decreased and 65 remained the same.

DR. T. B. HOLLOWAY, Philadelphia: Unfortunately in many cases of papilledema resulting from brain tumor, the intraocular examination has been summed up in a statement that there existed papilledema without any reference to its characteristics. If the question of the greater amount of swelling of the disc being homolateral or contralateral to the lesion is ever to be accurately determined, it seems to me that we must make and record certain definite ophthalmoscopic measurements, that have been elsewhere referred to.

As is well known, most statistics in the past have shown that the disc showing the greatest swelling is homolateral to

---

* A long article on this subject by Drs. G. E. De Schweinitz and T. B. Holloway, Philadelphia, appears in the Transactions of the Section on Ophthalmology, 1909, but will not appear in THE JOURNAL.

the lesion. A rather hurried search of the available cases recorded by Dr. De Schweinitz and myself, excluding those observed in the university and orthopedic hospitals, shows that the greatest swelling was homolateral in 50 per cent., contralateral in 20 per cent., and of equal extent in 30 per cent. of the cases.

In the few cases in which it was definitely stated which eye was first affected, it was found that the homolateral eye was, in the majority of cases, the first to show evidence of a papilledema. Likewise, in the majority of the cases, when the case histories revealed a record of the vision, it was found that the eye having the greatest impairment of vision was homolateral to the growth.

In reference to the rarity of papilledema in myopic eyes, I can recall but two cases that I have seen, and both of these were under observation at the Orthopedic Hospital in the service of Dr. Wharton Sinkler. In neither case was the myopia over 5 D. Paton refers to the macular fan which is seen in many cases of brain tumor as being due to a passive edema, in contradistinction to the macular fan seen in cases of nephritis which he refers to as being due to what he terms an active edema.

Recently I have had under observation a case associated with marked macular edema in which a typical macular fan developed, which was indistinguishable from that seen in the two conditions above referred to. Three weeks after the receipt of the injury, the first spots appeared in the temporal side of the fovea, in the direction of the greatest edema, and from three to four weeks later the figure was complete. The lesion responsible for its development was a penetrating wound of the eye from a piece of steel, the wound of exit being at the outer edge of the macular region. In reference to the subsidence of papilledema after the relief of intracranial tension in cases of brain tumor, but very few of the cases observed at the university and orthopedic hospitals have shown any distinct reduction in swelling prior to the third day. In this connection, it is interesting to refer to the unusual case observed by Thomas and Cushing. Prior to the operation the discs were reported as atrophic. The morning following the operation the patient developed symptoms of compression and an ocular examination revealed a papilledema of 4 D. A large clot was removed from the site of operation, after which the retinal edema began to subside in a few hours and by the second day the atrophic discs were as clear as before.

This case is analogous to the cases reported by Harlings Jackson, de Schweinitz and A. G. Thompson and E. R. Williams, although in these last named cases, the papilledema affected nerves that were completely atrophic.

Dr. Edward Stieren, Pittsburg: Since my report last year (*Ophthalmic Record*, March, 1908) of three cases of choked disc relieved by exploratory operation I have observed one case, in a woman, in which the general symptoms—headache, vomiting and staggering gait—were relieved by a decompressive operation but in which the vision is progressively becoming worse. The case is one of undoubted cerebellar tumor, under observation for about a month before a right temporal decompressive operation was performed by Dr. J. J Buchanan. Before operation R. V. = 6/80, L. V. = 6/16—with 8 and 7 D. elevation of the discs, respectively. No perceptible decrease in the papilledema could be observed for two weeks following the operation, when the discs gradually receded, although well-marked signs of optic neuritis persisted, optic atrophy intervening and steadily progressing. At present R. V. = 2/200, L. V. = 6/60 eccentrically. I am inclined to attribute the disappointing result in this case to either a cancer toxemia of the optic nerves, the patient's general appearance suggesting a cancerous cachexia, her damaged third nerves being unable to combat the onslaught of toxic irritants. Or, as Dr. Cushing suggests in this class of cases, it may be due to direct involvement of the optic tracts. In the case reported by me and quoted by the essayists as the patient having lived a little less than five months after operation, I desire to say that instead the man lived more than three years after operation, which, in view of the enormous size of the growth attained, as shown by the illustration, is remarkable.

Dr. R. L. Randolph, Baltimore: I was struck with the fact that the results of the experiments of Drs. Frazier and de Schweinitz were entirely at variance with those of Drs. Bordley and Cushing. I should like to ask Dr. Frazier what animals were employed, and whether these animals and the technic were similar to those used by Bordley and Cushing. Furthermore, I should like to know whether he has ever seen in animals anything approaching the picture which we see in human beings and which is called choked disc, and, if so, whether it resulted from high tension alone within the brain or whether it resulted from high tension plus something else. Personally, I have always held that high tension within the brain was a potent factor—probably the most potent factor—in the production of the so-called choked disc, but I believe that there are other essential factors, in the absence of which, no matter how high the tension, choked disc will not be seen.

Dr. William H. Wilder, Chicago: I should like to mention some points in a case I have under observation, which illustrated the correctness of the statements of Dr. Spiller relative to the effect of the hernia of the brain that occurs after decompression operations. The case is that of a young Scandinavian about 20 years of age who came into my service at the Illinois Eye and Ear Infirmary last winter. He gave a rather indefinite history of headaches, no vomiting, and no marked symptoms of brain tumor. There was an apparent mental dulness. There was a marked papillitis, about 7 D. of swelling, with edema and slight hemorrhages in the surrounding retina. Dr. Hugh T. Patrick, who examined him, agreed that there was probably an intracranial growth, but could discover no localizing signs, although he suspected that the tension was on the left side and advised a decompression operation.

Dr. A. E. Halstead operated, removing a large piece of bone from the parietal and temporal region. The bone was extremely thin from pressure, and after section of the dura the brain protruded to such an extent that the flap was replaced with difficulty. The shock of the operation was great. Soon after recovery, the patient began to show a weakness of the right hand, and then paresis, and finally paralysis of the right hand, arm and lower muscles of the face. There was also ataxic aphasia. This condition lasted fully three months and was probably caused by the pressure of the motor area of the brain against the margin of the opening in the skull. Gradually the man recovered in part his speech, and also the power of his right hand and arm. The swelling of the nerve head receded, reaching about 4 D., which it was when I saw him about five weeks ago, with the vision about 20/50, as good as when I first saw him.

It seems to me that there is something more than intracranial pressure in the etiology of these cases of papillitis or papilledema. The theory as stated by Leber that the products of metabolism in the tumor, circulating in the lymph channels, and so coming in contact with the nerve and exciting a true neuritis, associated, it is true, with edema, is a very plausible one. A patient presented at the Chicago session by Dr. Peter Bassoe on whom Dr. Bevan had operated was possibly one of this kind. The man had a pronounced papillitis with 7 D. of swelling, which was not reduced by the decompression operation. At a second operation the tumor was located and removed, with disappearance of the papillitis and restoration of vision.

Dr. William G. Spiller, Philadelphia: I fully believe that decompression is a very valuable means of saving sight and of affording relief from certain symptoms, but I think it an operation which should not be performed hastily, and without careful study of the patient. It seems so simple to bore a hole under the temporal muscle that we may be inclined to advise it without due consideration. I had a patient who had grave symptoms of brain tumor, and I advised decompression. The man sank into a marked stupor, and has remained in that state ever since. The effect of decompression in this case is uncertain. Following decompression we may have graver symptoms from hemorrhage from a bleeding vessel which has escaped the surgeon's attention, or which has occurred after the wound has been closed; and hemiplegia may develop.

The hemiplegia which occurs in these cases develops soon after the operation and should lead to an exposure of the wound and a search for the clot and attempt at its removal. But, aside from that, there is a hemiplegia that develops in certain cases later in the course of the disease, perhaps a week or two after the operation. That form of hemiplegia is not always caused by hemorrhage either on or in the brain. In the past few weeks I have had opportunity to examine a brain from such a case, and I found that the hemiplegia was caused by an occlusion of the blood vessels by a hernia that occurred; the brain protruding through the opening in the bone and causing pressure directly on the vessels. We are inclined to think that the hernia produced after decompression is indicative of the growth of the tumor, and to say that the hernia shows exactly how much we have benefited the patient by relief of pressure, as otherwise the tumor would have grown and possibly have caused death. This conclusion is not invariably correct, but is correct in certain cases. The hernia may occur from causes we do not understand. While, therefore, I believe fully in decompression in suitable cases, and feel that it may be of great use, I also feel that we must study every case carefully before advising it.

Dr. Albert E. Bulson, Jr., Fort Wayne, Ind.: During the last eighteen months I have had four patients on whom the decompression operation was done. In two of the cases I was much gratified with the results of the operation so far as its effect on the vision was concerned. In all the cases a competent neurologist was consulted with the idea of making a diagnosis of the probable location of the tumor, but in two of the cases it was impossible for him to arrive at any definite conclusions, though he agreed as to the necessity for a decompression operation to save the vision, which was very rapidly failing. In one of the cases there was, within a few days following the decompression operation, an increase in the vision which was retained for several months. In this case, as well as in one other case, it was found later on autopsy that the tumor would in all probability have been located during the patient's life had the development of localizing pressure symptoms caused by the growth of the tumor not been disturbed by the decompression operation. It is therefore presumed that a little delay in the performance of the decompression operation might have resulted in prolonging the life of the patient through the localization and removal of the tumor. The decompression operation should be performed with a view of removing the tumor if possible, though with rapidly failing vision due to intracranial pressure and no localizing symptoms, the decompression operation in the silent zone is indicated and should be performed with a view of saving vision. We should always take into consideration the fact that the patient's life is in danger and the saving of vision is not as important as the saving of life. Some tumors can be removed and the life, as well as the vision, saved for many years.

Dr. B. A. Randall, Philadelphia: Out of a limited experience in this matter I would cite a recent case referred by Dr. S. Z. Shope of Harrisburg, Pa., which is interesting because the edema was extreme—8 or 9 D. There had been the question, also, if the rapidly increasing swelling could be due to lesion of the nasal accessory cavities. The eyesight was rapidly declining and there was no marked involvement of the nasal cavities. The patient, a girl of 20, had a clear history of specific inheritance, but no stigmata; and there had been a bad fall with a possibility of cystic growth. The neurologist regarded it as a case of neoplasm of the right motor region and urged not only decompression but exploration as to the presence and operability of the growth. Making a good-sized osteoplastic flap, I found great tension of the dura and on incising it, there was marked protrusion of the brain substance. I relieved this greatly by lumbar puncture, having had much question whether lumbar puncture would not have been safe and adequate. I then exposed and examined the motor convolutions more freely, and seeing and feeling no growth, sutured the dura and replaced the flap. The case had been admirable in its outcome thus far, but done on April 29 it is too soon to know the issue. Vision is restored in the left eye, the edema is almost gone in both, but the field is somewhat narrowed on the right and the lesions near the macula, simulating those of albuminuric retinitis, interfere greatly with its recovery. Whereas she had seemed stuffed up by small doses of iodid, she is now taking 33 grains three times daily and all symptoms are ameliorating. This seems merely a case of relieving destructive pressure until we could get the influence of our medication, unless we are wholly in error as to the specific nature of the lesion.

Dr. Nelson M. Black, Milwaukee, Wis.: As to not finding choked disc following head injuries, I would like to state that through the kindness of Dr. Charles Lemon, surgeon of the Milwaukee Electric Street Railway, I have had the opportunity of making ophthalmoscopic examination of cases of head injuries following street-car accidents. In one case there was a distinct choked disc of about 1½ D on the side opposite to the injury and a complete blurring and loss of contour of the disc margin on the side of the injury. This entirely disappeared within four or five days after decompression. In a second case, there was decided blurring of the disc margins equal in both eyes, which gradually cleared up in about two weeks; the temporal side of the disc clearing first; no decompression was done. In a third case, a man fell from a scaffold about fifty feet, landing on his head and shoulders; he was brought into hospital unconscious and when placed on the operating table stopped breathing. Artificial respiration was instituted and a decompression operation immediately done. As soon as the dura was opened a considerable amount of pinkish cerebrospinal fluid gushed out and the patient began to breathe. The ophthalmoscope showed nothing abnormal beyond decidedly hyperemic discs; but the decompression was done within an hour following the injury, so there was hardly time for the discs to become choked.

Dr. G. E. de Schweinitz, Philadelphia: The existence of choked disc does not always indicate operative interference. Naturally, prolonged and careful study must always be given to each patient before he is submitted to operation, and all means at our disposal which will help to establish a diagnosis should be brought into requisition. This is particularly true in such cases as may be due to syphilis, and the serum reaction for the detection of this infection, not only that of Wassermann, but its substitutes, so well discussed in the Section on Nervous and Mental Diseases, will doubtless prove of great service under such conditions. Moreover, each one of us should study most carefully the visual field phenomena to which Bordley has made reference. You have heard from him the interesting observations which he and Dr. Cushing have made, now, to be sure, only in their earliest stages, and it behooves all of us, whenever opportunity presents, to undertake similar examinations.

It has been known for many years that such alterations of the visual field occur in cases of brain tumor, and other organic diseases, but so far as I am aware, no such study has been given the subject as that which has been accorded to it by Dr. Bordley and Dr. Cushing, nor have the results which they have reached ever before been published.

While I am satisfied that one of the factors in the production of papilledema is increased intracranial tension, and am inclined to believe that it is the most important factor, I feel sure that it can not be the only one. In our experiments to which Dr. Frazier has made reference we never succeeded in the living eye in producing anything like the ophthalmoscopic picture of papilledema when a pure physiologic salt solution was used in subdural injections. On the other hand, if we added irritating substances to the fluid, formaldehyd, iodin, etc., we did succeed in producing, not a very pronounced but none the less a definite swelling of the optic nerve. Different results have been reached in the Johns Hopkins Hospital by Drs. Cushing and Bordley. Sometime or other we propose to exchange laboratory visits in order to see wherein either our technic or our results have differed.

Dr. Charles H. Frazier, Philadelphia: I have been asked whether we followed in the experimental work in papilledema the technic used in the Cushing-Bordley experiments. I am not familiar with the technic referred to; we purposely did not follow the method of previous investigators because we wanted to conduct our experiments with an open mind and entirely uninfluenced by the results of previous observers. As Dr. de Schweinitz has said, intracranial tension must be an etiologic factor; while admitting this, we are sure that it is not the only nor even the essential factor. Since the report was published, we have added to the physiologic salt solution certain irritating substances such as iodin and formaldehyd, and we are led to believe that these substances have some effect on the etiology of papilledema independent of intracranial tension. We have never yet seen papilledema in the dog similar to that observed in the human subject under analogous conditions.

Dr. Spiller cautions us against too frequent and too hasty resort to decompression. On the other hand, the operation should not be put off too long. I feel I have altogether too many patients absolutely blind, whose vision might have been preserved. Selecting at random for student demonstration five patients already operated on, I found in three out of the five that vision had been practically lost. From six weeks to two months is long enough to wait for improvement under the iodids and mercury, for the localization of the tumor, or for the confirmation of the diagnosis. If at the expiration of this time the papilledema is stationary, or increasing, side decompression should be practiced without further delay.

I have been asked whether, rather than resort too soon to decompression, we should not wait for the development of such symptoms as would suggest the situation of the tumor. I should say emphatically no. At any time after the decompression the radical operation may be performed and just as soon as focal symptoms make their appearance. The preliminary palliative procedure which relieves headache and vomiting and preserves vision, does not preclude the possibility of subsequently operating for the removal of the tumor. In some cases it delays development of the symptoms, but we are justified in operating early to relieve the subjective symptoms, especially when we know that in not more than one case in ten will the tumor prove to be operable.

A word as to the undesirable results of decompression: Dr. Wilder has referred to a case in which, after decompression on the left side, hemiplegia and aphasia developed. I have had a similar experience, but the hemiplegia and aphasia entirely disappeared in the course of a few weeks. These disturbances are often associated with a sudden increase in the size and tension of the hernia which forms at the site of the opening—a phenomenon which I have attributed to the disturbance of the circulation in the herniated portion. The pressure of the margins of the bony opening interferes with the return venous circulation and this in turn is followed by edema. It might be said in this connection that we always decompress on the right side unless there are *some contraindications* for so doing. The right side, as pointed out by Sänger, is the site of election because it uncovers the silent area of the brain in all cases.

Some reference was made to observations which we have made in the relation of papilledema to intracranial trauma. I do not mean to say papilledema of traumatic origin does not occur, for I know it does in a few instances, but much more infrequently than we have been led to believe by certain published statements. But papilledema of traumatic origin is only transitory and will subside without surgical intervention. The routine resort to operation, within twenty-four or forty-eight hours of the accident, is neither necessary nor justifiable. This point was strikingly illustrated by a case under my observation this year. The man had evidently a basal fracture with occurrence of papilledema, but as the man's life was not threatened, we dismissed at once the question of operation, and within a week of the injury the patient developed paralysis of face and arm on one side. We then explored and found in the cortex a small blood clot, the removal of which relieved the focal symptoms. In this case had we resorted to immediate decompression, the man would have had to have two operations.

Pasteurization.—This does not mean simply the heating of milk; the subsequent rapid cooling is a very important part of the process.—M. J. Rosenau, in *Annals of Medical Practice.*

Clinical Notes

A NEW METHOD OF TENDON-SHORTENING

WITHOUT SEVERING THE TENDON AND WITHOUT THE USE OF NEEDLE AND SUTURE *

H. H. BRIGGS, M.A., M.D.
ASHEVILLE, N. C.

The method is applicable to any case in which shortening of an ocular muscle is indicated. The principle involved is the looping of the tendon and maintaining the shortening thus attained by means of a silver link (Fig. 1) clamped over the loop and retained there until inflammatory adhesion takes place between the advanced portion of tendon and the sclera. The link, elliptical in shape, is made of silver wire (No. 20, Brown and Sharpe Standard). It is long enough to extend across the tendon, and wide enough to allow a small tendon hook with the looped tendon and overlying conjunctiva to pass through its lumen. The major axis of the link should be about 5 mm., the minor about 2 mm. Pure silver wire gives the proper amount of resiliency, retains its compressed shape, is easily removed and seems to serve better than an alloy. To insure against the tendon retracting through the link, burrs may be punched on the inner surface of the link to act as barbs against the pulling action of the tendon.

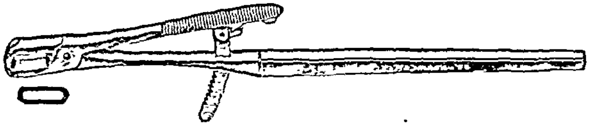

Fig. 1. Silver link and clamp forceps for use in tendon-shortening operation (forceps three-fifths size; link full size).

A clamp forceps (Fig. 1) is used to grasp the silver link in its jaws and hold it in position over the tendon until the loop of tendon and conjunctiva is drawn up through the link, when by compressing the forceps the link is compressed sufficiently firm over the loop to maintain the loop the required time after the forceps has released the link and left it *in situ.* Passing entirely across the approximating surface of the jaws near the tips are transverse grooves deep enough to hold the long parallel sides of the silver link. The length of jaw to the angle is sufficient to accommodate the longest loop of tendon that may be desired. A ratchet maintains the jaws in any compressed position over the link.

Fig. 2. Special tendon hook (three-fifths size).

A special tendon hook (Fig. 2) is used, differing from the ordinary small tenotomy hook in that its shank, 6 mm. above its angle, is bent backward in the plane of the hook at an angle of about 15 degrees. This bend allows the handle of the tendon hook to be held out of the operator's line of vision, and at the same time the hook may remain parallel to the tangent plane of the eye at the site of operation. The hook should be short enough to pass through the major axis of the link, and yet sufficiently long and strong to pull the tendon through the link, overcoming the pull of the opponent muscle, which may or may not have been previously tenotomized.

For removal of the link a scissors forceps with wedge-shaped blade above and flat blade below (Fig. 3) is

The hemiplegia which occurs in these cases develops soon after the operation and should lead to an exposure of the wound and a search for the clot and attempt at its removal. But, aside from that, there is a hemiplegia that develops in certain cases later in the course of the disease, perhaps a week or two after the operation. That form of hemiplegia is not always caused by hemorrhage either on or in the brain. In the past few weeks I have had opportunity to examine a brain from such a case, and I found that the hemiplegia was caused by an occlusion of the blood vessels by a hernia that occurred: the brain protruding through the opening in the bone and causing pressure directly on the vessels. We are inclined to think that the hernia produced after decompression is indicative of the growth of the tumor, and to say that the hernia shows exactly how much we have benefited the patient by relief of pressure, as otherwise the tumor would have grown and possibly have caused death. This conclusion is not invariably correct, but is correct in certain cases. The hernia may occur from causes we do not understand. While, therefore, I believe fully in decompression in suitable cases, and feel that it may be of great use, I also feel that we must study every case carefully before advising it.

Dr. Albert E. Bulson, Jr., Fort Wayne, Ind.: During the last eighteen months I have had four patients on whom the decompression operation was done. In two of the cases I was much gratified with the results of the operation so far as its effect on the vision was concerned. In all the cases a competent neurologist was consulted with the idea of making a diagnosis of the probable location of the tumor, but in two of the cases it was impossible for him to arrive at any definite conclusions, though he agreed as to the necessity for a decompression operation to save the vision, which was very rapidly failing. In one of the cases there was, within a few days following the decompression operation, an increase in the vision which was retained for several months. In this case, as well as in one other case, it was found later on autopsy that the tumor would in all probability have been located during the patient's life had the development of localizing pressure symptoms caused by the growth of the tumor not been disturbed by the decompression operation. It is therefore presumed that a little delay in the performance of the decompression operation might have resulted in prolonging the life of the patient through the localization and removal of the tumor. The decompression operation should be performed with a view of removing the tumor if possible, though with rapidly failing vision due to intracranial pressure and no localizing symptoms, the decompression operation in the silent zone is indicated and should be performed with a view of saving vision. We should always take into consideration the fact that the patient's life is in danger and the saving of vision is not as important as the saving of life. Some tumors can be removed and the life, as well as the vision, saved for many years.

Dr. B. A. Randall, Philadelphia: Out of a limited experience in this matter I would cite a recent case referred by Dr. S. Z. Shope of Harrisburg, Pa., which is interesting because the edema was extreme—8 or 9 D. There had been the question, also, if the rapidly increasing swelling could be due to lesion of the nasal accessory cavities. The eyesight was rapidly declining and there was no marked involvement of the nasal cavities. The patient, a girl of 20, had a clear history of specific inheritance, but no stigmata; and there had been a bad fall with a possibility of cystic growth. The neurologist regarded it as a case of neoplasm of the right motor region and urged not only decompression but exploration as to the presence and operability of the growth. Making a good-sized osteoplastic flap, I found great tension of the dura and on incising it, there was marked protrusion of the brain substance. I relieved this greatly by lumbar puncture, having had much question whether lumbar puncture would not have been safe and adequate. I then exposed and examined the motor convolutions more freely, and seeing and feeling no growth, sutured the dura and replaced the flap. The case had been admirable in its outcome thus far, but done on April 29 it is too soon to know the issue. Vision is restored in the left eye, the edema is almost gone in both, but the field is somewhat narrowed on the right and the lesions near the macula, simulating those of albuminuric retinitis, interfere greatly with its recovery. Whereas she had seemed stuffed up by small doses of iodid, she is now taking 33 grains three times daily and all symptoms are ameliorating. This seems merely a case of relieving destructive pressure until we could get the influence of our medication, unless we are wholly in error as to the specific nature of the lesion.

Dr. Nelson M. Black, Milwaukee, Wis.: As to not finding choked disc following head injuries, I would like to state that through the kindness of Dr. Charles Lemon, surgeon of the Milwaukee Electric Street Railway, I have had the opportunity of making ophthalmoscopic examination of cases of head injuries following street-car accidents. In one case there was a distinct choked disc of about 1½ D on the side opposite to the injury and a complete blurring and loss of contour of the disc margin on the side of the injury. This entirely disappeared within four or five days after decompression. In a second case, there was decided blurring of the disc margins equal in both eyes, which gradually cleared up in about two weeks; the temporal side of the disc clearing first; no decompression was done. In a third case, a man fell from a scaffold about fifty feet, landing on his head and shoulders; he was brought into hospital unconscious and when placed on the operating table stopped breathing. Artificial respiration was instituted and a decompression operation immediately done. As soon as the dura was opened a considerable amount of pinkish cerebrospinal fluid gushed out and the patient began to breathe. The ophthalmoscope showed nothing abnormal beyond decidedly hyperemic discs; but the decompression was done within an hour following the injury, so there was hardly time for the discs to become choked.

Dr. G. E. de Schweinitz, Philadelphia: The existence of choked disc does not always indicate operative interference. Naturally, prolonged and careful study must always be given to each patient before he is submitted to operation, and all means at our disposal which will help to establish a diagnosis should be brought into requisition. This is particularly true in such cases as may be due to syphilis, and the serum reaction for the detection of this infection, not only that of Wassermann, but its substitutes, so well discussed in the Section on Nervous and Mental Diseases, will doubtless prove of great service under such conditions. Moreover, each one of us should study most carefully the visual field phenomena to which Bordley has made reference. You have heard from him the interesting observations which he and Dr. Cushing have made, now, to be sure, only in their earliest stages, and it behooves all of us, whenever opportunity presents, to undertake similar examinations.

It has been known for many years that such alterations of the visual field occur in cases of brain tumor, and other organic diseases, but so far as I am aware, no such study has been given the subject as that which has been accorded to it by Dr. Bordley and Dr. Cushing, nor have the results which they have reached ever before been published.

While I am satisfied that one of the factors in the production of papilledema is increased intracranial tension, and am inclined to believe that it is the most important factor, I feel sure that it can not be the only one. In our experiments to which Dr. Frazier has made reference we never succeeded in the living eye in producing anything like the ophthalmoscopic picture of papilledema when a pure physiologic salt solution was used in subdural injections. On the other hand, if we added irritating substances to the fluid, formaldehyd, iodin, etc., we did succeed in producing, not a very pronounced but none the less a definite swelling of the optic nerve. Different results have been reached in the Johns Hopkins Hospital by Drs. Cushing and Bordley. Sometime or other we propose to exchange laboratory visits in order to see wherein either our technic or our results have differed.

Dr. Charles H. Frazier, Philadelphia: I have been asked whether we followed in the experimental work in papilledema the technic used in the Cushing-Bordley experiments. I am not familiar with the technic referred to; we purposely did not follow the method of previous investigators because we wanted to conduct our experiments with an open mind and entirely uninfluenced by the results of previous observers. As Dr. de Schweinitz has said, intracranial tension must be an etiologic factor; while admitting this, we are sure that it is not the only nor even the essential factor. Since the report was published, we have added to the physiologic salt solution certain irritating substances such as iodin and formaldehyd, and we are led to believe that these substances have some effect on the etiology of papilledema independent of intracranial tension. We have never yet seen papilledema in the dog similar to that observed in the human subject under analogous conditions.

Dr. Spiller cautions us against too frequent and too hasty resort to decompression. On the other hand, the operation should not be put off too long. I feel I have altogether too many patients absolutely blind, whose vision might have been preserved. Selecting at random for student demonstration five patients already operated on, I found in three out of the five that vision had been practically lost. From six weeks to two months is long enough to wait for improvement under the iodids and mercury, for the localization of the tumor, or for the confirmation of the diagnosis. If at the expiration of this time the papilledema is stationary, or increasing, side decompression should be practiced without further delay.

I have been asked whether, rather than resort too soon to decompression, we should not wait for the development of such symptoms as would suggest the situation of the tumor. I should say emphatically no. At any time after the decompression the radical operation may be performed and just as soon as focal symptoms make their appearance. The preliminary palliative procedure which relieves headache and vomiting and preserves vision, does not preclude the possibility of subsequently operating for the removal of the tumor. In some cases it delays development of the symptoms, but we are justified in operating early to relieve the subjective symptoms, especially when we know that in not more than one case in ten will the tumor prove to be operable.

A word as to the undesirable results of decompression: Dr. Wilder has referred to a case in which, after decompression on the left side, hemiplegia and aphasia developed. I have had a similar experience, but the hemiplegia and aphasia entirely disappeared in the course of a few weeks. These disturbances are often associated with a sudden increase in the size and tension of the hernia which forms at the site of the opening—a phenomenon which I have attributed to the disturbance of the circulation in the herniated portion. The pressure of the margins of the bony opening interferes with the return venous circulation and this in turn is followed by edema. It might be said in this connection that we always decompress on the right side unless there are some contraindications for so doing. The right side, as pointed out by Sänger, is the site of election because it uncovers the silent area of the brain in all cases.

Some reference was made to observations which we have made in the relation of papilledema to intracranial trauma. I do not mean to say papilledema of traumatic origin does not occur, for I know it does in a few instances, but much more infrequently than we have been led to believe by certain published statements. But papilledema of traumatic origin is only transitory and will subside without surgical intervention. The routine resort to operation, within twenty-four or forty-eight hours of the accident, is neither necessary nor justifiable. This point was strikingly illustrated by a case under my observation this year. The man had evidently a basal fracture with occurrence of papilledema, but as the man's life was not threatened, we dismissed at once the question of operation, and within a week of the injury the patient developed paralysis of face and arm on one side. We then explored and found in the cortex a small blood clot, the removal of which relieved the focal symptoms. In this case had we resorted to immediate decompression, the man would have had to have two operations.

Pasteurization.—This does not mean simply the heating of milk; the subsequent rapid cooling is a very important part of the process.—M. J. Rosenau, in *Annals of Medical Practice.*

Clinical Notes

A NEW METHOD OF TENDON-SHORTENING

WITHOUT SEVERING THE TENDON AND WITHOUT THE USE OF NEEDLE AND SUTURE *

H. H. BRIGGS, M.A., M.D.
ASHEVILLE, N. C.

The method is applicable to any case in which shortening of an ocular muscle is indicated. The principle involved is the looping of the tendon and maintaining the shortening thus attained by means of a silver link (Fig. 1) clamped over the loop and retained there until inflammatory adhesion takes place between the advanced portion of tendon and the sclera. The link, elliptical in shape, is made of silver wire (No. 20, Brown and Sharpe Standard). It is long enough to extend across the tendon, and wide enough to allow a small tendon hook with the looped tendon and overlying conjunctiva to pass through its lumen. The major axis of the link should be about 5 mm., the minor about 2 mm. Pure silver wire gives the proper amount of resiliency, retains its compressed shape, is easily removed and seems to serve better than an alloy. To insure against the tendon retracting through the link, burrs may be punched on the inner surface of the link to act as barbs against the pulling action of the tendon.

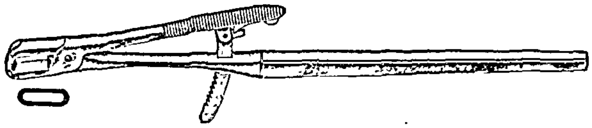

Fig. 1. Silver link and clamp forceps for use in tendon-shortening operation (forceps three-fifths size; link full size).

A clamp forceps (Fig. 1) is used to grasp the silver link in its jaws and hold it in position over the tendon until the loop of tendon and conjunctiva is drawn up through the link, when by compressing the forceps the link is compressed sufficiently firm over the loop to maintain the loop the required time after the forceps has released the link and left it *in situ*. Passing entirely across the approximating surface of the jaws near the tips are transverse grooves deep enough to hold the long parallel sides of the silver link. The length of jaw to the angle is sufficient to accommodate the longest loop of tendon that may be desired. A ratchet maintains the jaws in any compressed position over the link.

Fig. 2. Special tendon hook (three-fifths size).

A special tendon hook (Fig. 2) is used, differing from the ordinary small tenotomy hook in that its shank, 6 mm. above its angle, is bent backward in the plane of the hook at an angle of about 15 degrees. This bend allows the handle of the tendon hook to be held out of the operator's line of vision, and at the same time the hook may remain parallel to the tangent plane of the eye at the site of operation. The hook should be short enough to pass through the major axis of the link, and yet sufficiently long and strong to pull the tendon through the link, overcoming the pull of the opponent muscle, which may or may not have been previously tenotomized.

For removal of the link a scissors forceps with wedge-shaped blade above and flat blade below (Fig. 3) is used to divide each end, when the severed halves of the link may be removed with small tissue forceps.

---

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

After the usual preparation of sterilization and anesthetization, the operator, standing on the side of the eye nearest the muscle to be shortened, makes a small opening in the conjunctiva on one side (the operator's right side) of the tendon near its insertion into the sclera, the distance from the insertion varying with the degree of advancement intended. An ordinary tenotomy hook passed beneath the tendon is held by an assistant, the clamp forceps holding the silver link is held over the tendon with one hand, and the special tendon hook passed down through the silver link is substituted for the hook held by the assistant. The tendon with its overlying conjunctiva is drawn up through the link to the desired degree, and the jaws of the clamp forceps forcibly approximated. If the degree of deviation is great, and the tendon loop to be made long, the conjunctiva, after being drawn up through the link a short distance, may be incised, allowing the tendon only to be advanced to any desired degree. It may be necessary in excessive advancements to excise the greater part of tendon and tissues protruding through the link, leaving only enough to insure non-retraction of the tendon ends through the link.

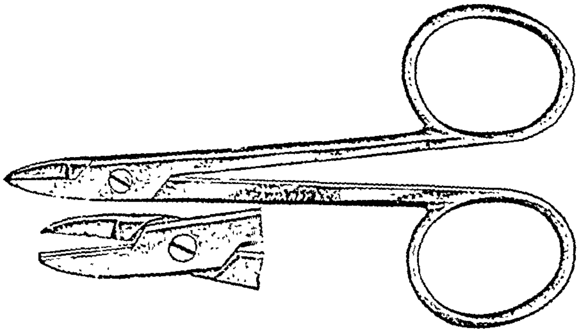

Fig. 3. Scissors forceps with wedge-shaped blade above and flat blade below, for severing link (full size).

The moderate edema of the tissues about the link immediately covers it so that no irritation is felt from the presence of the foreign body. Within twenty-four hours the strangulated tissues become white and begin to atrophy, and on removal of the loop in ten to fourteen days they should be excised.

The advantages of this operation over the usual methods of advancement are:

1. Simplicity.
2. Elimination of sutures.
3. Avoidance of tenotomy of the advanced muscle.
4. Absolute security from slipping or retraction of tendon.
5. Short duration of time of operation.
6. Less pain.
7. Less amount of plastic inflammation during convalescence.
8. Short period of convalescence.
9. Less scar and deformity.
10. Better results.

29 Haywood Street.

Eclampsia with Vesicular Mole.—E. Gross reports a case of eclampsia in a ii-para of 22 at the fifth month of pregnancy. The fetus and a large placenta partially transformed into a vesicular mole were expelled twelve hours after the first symptoms, and the patient died 31 hours later. He has found six cases on record of eclampsia with mole, and in the *Prager med. Wchnschr.*, July 1, discusses the frequency of moles and also of eclampsia at the fifth month of pregnancy.

EXCISION OF A TUBERCULOUS HIP-JOINT IN A WOMAN OF FIFTY

HARRY GREENBERG, M.D.
MILWAUKEE

In view of the prevailing opinion among surgeons, that radical excision of the hip-joint for tuberculosis should not be attempted after the fourteenth or fifteenth year, the following case will be of interest:

History.—Mrs. J. E. H., aged 50, had had tuberculosis of the right hip since she was 18 months old. In spite of the most diligent application of conservative treatment, she would continue to have relapses at intervals varying from five to ten years. At no time could a positive prognosis as to complete cure be assured. Abscesses were opened and drained at various intervals. For the past ten years she had been apparently well excepting for periodic attacks of pain in the affected hip. At no time was she able to walk without assistance of some kind. Twenty-six months ago a new abscess formed and pointed in the groin; it was opened by her family physician. Two weeks later she came under my observation.

Examination.—She was suffering from acute infection; temperature, 105.4 F.; pulse, 140; complained of severe pain in the right leg. Examination showed the right hip-joint completely ankylosed. The right leg was seven and one-half inches shorter than the left, and five inches less in circumference at its middle. It was markedly adducted, overlapping the left leg. Abscess and sinuses were discharging freely.

Treatment.—Local palliative measures were immediately instituted and continued for ten days. Her temperature varied from 104 to 106 F. Morphin was used continuously to relieve the pain. She was then removed to the hospital for more radical treatment.

Operation.—The joint was freely opened and the following conditions found: The head and neck of the femur and most of the acetabulum were completely destroyed by the tuberculous process. What remained of the upper end of the femoral shaft was a thin shell still retaining the shape of the bone. A ragged hole marked the place from which the base of the neck of the femur formerly sprung. Strong bands of fibrous adhesions bound this thin shell of bone on the ilium to a point about 3¼ inches above and behind the acetabulum. Free pus was present. The adhesions were severed and 3½ inches of the upper end of the femur removed. The sawed-off end of the femur was then placed in contact with the lower border of the actabulum and the wound sutured and drained. A sterile dressing was applied and the patient put to bed. No fixation of any kind was applied.

Subsequent History.—She began to improve immediately. Two months after the operation she walked about on crutches; twelve months later she was able to get about the house without the aid of crutches, and now, twenty-six months after the operation, she is able to walk long distances without any assistance whatever. She can flex, rotate, adduct and abduct the limb freely; in fact, she now has nearly 90 per cent. of motion, which before the operation was zero. The limb is 3½ inches longer than at the time of operation. Skiagrams taken twenty months after resection show a fairly well-formed new head and neck, growing in the direction of the original head and neck, and these lie in normal position with the acetabulum. Her general health is splendid and she has gained twenty-five pounds.

CONCLUSIONS

The good results obtained in this case as well as in twelve other cases[1] I attribute to the technic of the operation and of the after-treatment as I carry them out. This, in the main, consists in the complete removal of the diseased bone and the elimination of fixed dressings of any kind in the after-treatment. It is my opinion that plaster-of-Paris casts, splints and other fixation appliances commonly used in these cases after operation are responsible for the many bad results following this operation. Not only are they an unnecessary burden to the already overweakened and exhausted patient, but they are also a potent cause of deformity; insomuch that they prevent normal muscular action, thus giving the upper sawed end of the femur full scope to wander away from its moorings. Left to themselves, the various groups of muscles attached to the femur, by their opposing functions, tend to keep the bone in its normal plane. And as normal muscular action is essential in the production of a normal blood supply to the parts, healing is greatly facilitated.

---

[1] In a paper read before the Wisconsin State Medical Society, July 2, 1909, to be published in the Wisconsin Medical Journal.

All this is exactly counteracted by the use of fixed dressings. In non-operative cases plaster-of-Paris casts applied prevent undue irritation by keeping the diseased bone at rest and apart. But since the diseased bone is removed in operative cases the application of a cast becomes superfluous. This case is of interest because:

1. Radical operation late in life seems feasible, or even practicable.
2. It proves how impossible it is for one to pronounce complete cure in cases treated conservatively.

OBSERVATIONS ON ALIMENTARY ALBUMINURIA BY MEANS OF THE ANAPHYLAXIS REACTION *

H. GIDEON WELLS, M.D.
CHICAGO

Alimentary albuminuria has commonly been assumed to be a simple filtration from the blood of a foreign protein, present in the blood only because it has been taken into the digestive tract in such large amounts that some of the protein has passed directly through the mucous membrane into the blood, without having been first decomposed into amino-acids and other cleavage products. The protein found in the urine was supposed to be the same as that which had been eaten in excess, both on theoretical grounds and because of the results of chemical investigations. The chemical methods available for the distinguishing of proteins so similar as serum albumin and egg albumin, however, are anything but satisfactory, and therefore the identity of the proteins found in the urine after eating large amounts of raw eggs was not positively established. With the discovery of the biologic test for proteins our resources were greatly increased, and we were for the first time provided with a delicate means of distinguishing between very similar proteins, provided they came from different species of animals. Naturally, it was not long before the biologic reaction was applied to the proteins of albuminous urine, the first question considered being whether the identity of the urinary proteins with the blood proteins could be established by this method. Leclainch and Vallee,[1] Mertens,[2] and Zuelzer[3] almost simultaneously experimented with the immunization of rabbits with the albuminous urine of nephritis. The French experimenters reported that the serum of such immunized rabbits reacted with albuminous urine and pleuritic exudates of man, but *not with human serum*, or with albuminous urine of cows or horses; therefore they concluded that the reaction was specific for the proteins of human exudates, but not of ordinary blood proteins. This rather remarkable result was not confirmed by either Mertens or Zuelzer, both of whom found that the serum of rabbits immunized with nephritic urine reacts with either nephritic urine or with human serum, and conversely, antihuman serum reacts with nephritic urine as well as with human serum. They therefore consider that at least one of the proteins of nephritic urine must be identical with a serum protein, thus proving the origin of urinary protein from the blood.

Ascoli[4] studied the occurrence of egg albumin in the urine after eating raw eggs, it having already been shown by Uhlenhuth[5] that by prolonged feeding of egg albumin to rabbits specific precipitins are developed in their blood, thus indicating the passage of egg albumin directly into the blood. As early as one to two hours after injection of egg albumin into rabbits, Ascoli found that the urine reacted with the appropriate antiserum for both egg albumin and rabbit serum albumin, the same result being obtained somewhat more slowly when the albumin was fed by mouth. In healthy men the presence of egg albumin in the blood could be demonstrated by the precipitin test as early as one and three-quarters hours after eating raw eggs, while in the urine both egg albumin and serum albumin can be demonstrated by the same method. Nephritics also excrete both egg albumin and serum albumin in the urine after eating raw eggs, according to the precipitin test. On account of the demonstration of the presence of both kinds of proteins in the urine, Ascoli concludes that the egg albumin when present in the blood so injures the renal cells that not only the foreign egg albumin, but also the normal serum proteins, escape into the urine. At times egg albumin may be demonstrable in the blood without the presence of any protein in the urine, a fact in harmony with the common observation that some healthy persons will show no albuminuria after eating even large quantities of raw eggs. In subsequent papers, Ascoli[6] reported observations to the effect that not only egg albumin, but also the proteins of beef and chicken, can be demonstrated in the blood and lymph shortly after these substances have been taken in the food; and when these proteins cause albuminuria the precipitin reaction will demonstrate in the urine not only the foreign protein but also the native serum proteins. Therefore, it would seem that foreign proteins are eliminated in the urine only through the injury which they produce in the kidney, and this injury makes it also temporarily permeable to the normal serum proteins. The finding of egg albumin by the precipitin test in human urine after eating raw eggs has been confirmed by others,[7] but so far as can be learned the presence of blood proteins in the urine in alimentary albuminuria has not been investigated except by Ascoli.

Cramer[8] states that the albuminous urine which is passed by rabbits after intraperitoneal injection of egg white does not give the precipitin reaction with antisera for either egg white or rabbit serum. Further, such urine, or the protein obtained from it, when injected repeatedly into rabbits, does not cause the rabbits' serum to react with either egg white or the isolated urinary protein. He believes that a negative precipitin test does not necessarily indicate the absence of the protein for which the serum used in the test is specific.

More recently Wilson[9] has applied the fixation of complement test to the detection of the nature of the albumin in human urine. This reaction is as specific as the precipitin reaction, and much more delicate, a reaction being obtained with as little as 0.00001 c.c. of human serum. Applied to urine it was found to be from 10 to 100 times more delicate than the nitric acid test, so that it was possible by this means to detect albumin in urine when there was no sign of albumin by chemical tests. He finds that the main protein element of albuminous urine has a human antigen, and therefore is presumably human protein, but he seems not to have sought for the presence of other proteins in either nephritis or alimentary albuminuria.

There exists not only a scientific interest in this question of alimentary albuminuria, but there is also some practical bearing, for it might at times be desirable to ascertain whether the albumin in a given sample of urine represents food protein or blood protein. While the precipitin test is of distinct value, yet its application is not readily made without more or less experience in immunologic work, and requires a good deal of time and labor in immunizing animals and preparing the specific serums. It therefore seemed possible that the anaphylaxis reaction might be found serviceable in this connection, in view of its simplicity and its delicacy, since a guinea-pig may be successfully sensitized with a dose of one-millionth of a gram of egg albumin, or even less. One has only to inject the urine, either fresh or preserved by chloroform, into the peritoneal cavity of a medium sized guinea-pig, best weighing 300 and 500 grams, and two weeks or more later inject intraperitoneally the sort of protein suspected of being in the urine. For the first or sensitizing dose of urine, from 1 to 5 c.c. according to the amount of albumin present, is a suitable dose; for the intoxicating dose, from 2 to 5 c.c. of ascites fluid or human serum, or a corresponding amount of egg white, is a proper amount.

The first experiment performed was as follows:

Experiment 1.—A healthy young man, whose urine contained no albumin by either the heat or the nitric acid tests, took three raw eggs for breakfast (8 a. m.), after having abstained from food containing eggs for three days. Urine passed at 10:30 a. m. contained no albumin by either heat or nitric acid tests. At 1:15 p. m. six more raw eggs were eaten. Urine passed at 1:30 p. m. contained no albumin. Urine passed at 3 p. m. gave a barely perceptible reaction for albumin; that passed at 6 p. m. gave a distinct reaction, and 8 p. m. again only a trace could be detected. Guinea-pigs were injected with doses of from 10 c.c. to 1 c.c. of each of these samples, and 16 days later they were again injected with either egg white or human ascites fluid.

The results were as follows: Injection of egg albumin into these pigs sensitized with urine caused no symptoms whatever, no matter what sample of urine or what dose had been used in sensitizing; in all, this was done to fifteen guinea-pigs with negative results. Neither did the specimen of urine containing the largest amount of albumin (6 p. m. sample) cause anaphylaxis symptoms when injected in 10 c.c. doses into guinea-pigs that had been sensitized with egg albumin two weeks previously, although the same pigs were killed by egg albumin injected 24 hours after the urine injection. However, when other pigs that had been sensitized with this urine were injected with 3 c.c. doses of human ascites fluid, the results were striking. The pigs sensitized with the urine passed before eating the eggs showed no symptoms whatever, but those receiving urine passed later, even the 10:30 a. m. sample which showed no albumin by the heat or nitric acid tests, all reacted violently to the human proteins of the ascites fluid. Most of the animals died, and the remainder were severely ill with the characteristic symptoms of the anaphylaxis reaction. The pigs that had been tested with egg albumin, which caused no reaction, reacted to a subsequent dose of ascites fluid quite as violently as the pigs which had received no egg albumin, which shows the specific character of the sensitization for human serum proteins.

These experiments indicate that the proteins present in the urine of this particular individual, after eating a large amount of egg albumin, are serum albumin, and that no unaltered egg albumin has escaped in the urine.

This result was not in harmony with the finding of Ascoli, who, as stated above, finds that the urine in alimentary albuminuria reacts with antiserums for both human protein and for egg albumin. It has, therefore, been repeated with three other healthy individuals with exactly the same results, as shown by the following abstracts of the experiments:

Experiment 2.—A healthy young man went without eggs for a day, then took six raw eggs for breakfast (8 a. m.) and again four more eggs at 12:30 p. m. Urine passed before eating the eggs, and also that passed at 12 o'clock, gave no reaction for albumin with either the nitric acid or the heat tests. At 4 p. m., however, it gave a very faint reaction for albumin. Guinea-pigs were sensitized with urine from each of these specimens, in doses from 1 to 10 c.c., and 16 days later were injected with either egg albumin (crystallized) in 0.1 gm. doses or human ascites fluid in 3 c.c. doses. None of the pigs receiving the egg albumin showed any symptoms whatever, while all the pigs receiving ascites fluid reacted typically, and in most instances severely, although none died. The pigs that had failed to react with albumin, when injected 24 hours later with ascites fluid reacted typically, showing conclusively that the sensitizing substance in this urine was not egg albumin, but human protein.

It is to be noted that the guinea-pigs which received the urine passed before eating the eggs also reacted to ascites fluid, although this urine gave no sign of reaction for albumin by either heat or nitric acid.

Experiment 3.—A healthy man, aged 33, who had been taking arsenic in small doses (1/40 grain t.i.d.) for several weeks without showing any trace of albumin in the urine, took the whites of 6 raw eggs for breakfast at 8 a. m. Specimens of urine were collected at 10:30 a. m. and 12:30 and 2:30 p. m.; only the last gave a possible reaction for albumin and this was questionable. As before, guinea-pigs in pairs were injected with samples of each specimen of urine, in doses from 2 to 10 c.c., and 20 days later they were injected with either egg albumin (0.1 gm. doses) or ascites fluid (3 c.c. doses). As before, none of the pigs injected with egg albumin reacted at all, while all the pigs injected with ascites fluid, including those that failed to react to egg albumin, reacted severely and typically, although not fatally. A specimen of morning urine passed two days after eating the raw eggs, and which showed no trace of albumin, in 5 c.c. doses sensitized guinea-pigs to ascites fluid so that they reacted typically but not severely.

Experiment 4.—A healthy young man, aged 29, whose urine showed no traces of albumin, ate the whites of six eggs at 7:30 a. m. Urine passed at 12:30 p. m. and at 5 p. m. showed no traces of albumin by the nitric acid or heat tests. Six guinea-pigs were injected with the urine passed at 12:30 and at 5 p. m. Twenty days later three were injected with 0.1 gm. egg albumin each and showed no symptoms; three were injected with human ascites fluid, and all reacted typically, those having received the 12:30 p. m. specimen more severely than the one sensitized with the 5 p. m. urine. The pigs that had failed to react to egg albumin were injected the next day with ascites fluid, and reacted exactly the same as the pigs that had not been given egg albumin. Of two pigs sensitized with the urine passed before eating the eggs, one did not react distinctly to ascites fluid, the other reacted slightly.

Experiment 5.—Two specimens of albuminous urine were obtained from nephritics, one containing but a trace of albumin, while the other gave a dense coagulum on heating.

---

[9] Jour. Path. and Bact., 1909, xiii, 484.

Guinea-pigs were injected with doses of these urines in quantities ranging from 10 to 0.1 c.c., and 19 days later they were injected with egg albumin or with ascites fluid. As before, the egg albumin had no effect, while the ascites fluid caused severe, frequently fatal intoxication, showing that the ordinary albuminous urine of nephritis contains human protein.

One fact noticeable in all the foregoing experiments was that animals which received 10 c.c. sensitizing doses of urine reacted less violently to the intoxicating dose of ascites fluid than the animals that received smaller doses of urine. This can not be explained as due to excessive quantity of protein in the sensitizing dose, for it was noticeable when the injected urine contained too little albumin to react with nitric acid. It is possible that urine, as well as other body fluids, contains substances that have an inhibiting effect on the anaphylaxis reaction, for in experiments performed with crystallized egg albumin and natural egg white it was found that unpurified egg white produced the reaction only when used in much larger doses than would be expected from its content of albumin;[10] contrasted with crystallized egg albumin the unpurified mixed proteins of egg white are about one-fifth as toxic for sensitized guinea-pigs, and but about one-hundredth as active in sensitizing.

A number of experiments were performed to determine the presence of protein in normal human urine by means of the anaphylaxis reaction. Morning urine from five healthy young men was injected into guinea-pigs in 1, 5 and 10 c.c. doses, and after an interval of three weeks human ascites fluid was injected in doses of 3 c.c. In nearly all cases the animals showed typical anaphylaxis symptoms of greater or less severity, but in only a few instances was the reaction fatal. From this it would seem that minute quantities of protein are present in the urine of normal individuals, and that this protein, which is too small in amount to be detected by the heat or nitric acid tests, possesses the specific properties of human proteins, like the proteins present in albuminuria.

SUMMARY

Although a few observers report having found evidence of the presence of specific food proteins in the urine in alimentary albuminuria by means of the precipitin reaction, yet by the anaphylaxis reaction the results are found to be quite different. Guinea-pigs sensitized with urine from four healthy persons with experimental alimentary albuminuria, produced by eating raw eggs, and with urine from two cases of nephritis, reacted typically and severely to subsequent injections of human ascites fluid, and not at all to egg white or to egg albumin. In view of the extremely minute quantity of protein necessary to sensitize guinea-pigs to the homologous protein, these results speak against the prevalent view that the albumin present in the urine in alimentary albuminuria is the same protein that has been taken in the food. Either the ingested and absorbed protein is altered to the extent of acquiring specific human properties before being eliminated in the urine, or else it is not excreted at all, but injures the kidneys slightly and transitorily by overloading the blood with nitrogenous waste products, so that they become permeable to the normal proteins of the serum. If the results of the anaphylaxis reaction alone were considered, the latter explanation would seem to be the most probable, but several observers report that the urine in alimentary albuminuria reacts with specific precipitins for the food proteins. This discrepancy between the results of experiments with the precipitin and the anaphylaxis reactions may be interpreted as meaning that the two methods are not of equal value in solving the problem, or it may be suggested that the precipitin reaction is given by food proteins that have been slightly altered during the processes of absorption and excretion so that they will not sensitize guinea-pigs to the original protein. However, experiments to be reported elsewhere show that digestion of proteins very quickly destroys their property of reacting with precipitins, while the anaphylactic properties of protein resist destruction by either peptic or tryptic digestion for a remarkably long time.

In any case, there can be no question that even in alimentary albuminuria, as well as in nephritis, the urinary proteins are chiefly, perhaps exclusively, human proteins, and, therefore, presumably derived from the blood rather than from the food. Whether any of the unaltered food protein reaches the urine is doubtful, because of the disagreement on this point of the anaphylaxis reaction and the precipitin reaction. Further comparative studies are needed to clear up this point, both because of the desirability of knowing just what relation the precipitin and anaphylaxis reactions have to each other, and because of the importance to the physiologist of definite information as to whether unaltered food proteins can pass through the intestinal wall.

On account of the delicacy of the anaphylaxis reaction it shows the presence of human proteins in urine from normal persons, which gives no reaction for albumin by the heat or nitric acid tests.

A FEW POINTS ON PROPHYLAXIS OF TUBERCULOSIS

J. CLEMENT JENKINS, M.D.
LITITZ, PA.

It is important to prevent future generations from contracting tuberculosis by a thorough course of preventive medicine and hygiene taught in our public schools. Germs are everywhere, and it is essential not to disseminate the pathogenic varieties. Expectoration in the open air should not be tolerated.

We must treat properly the cases already under our observation. Individuals suffering with tuberculosis should be cautioned against marrying. If the married state hastens the progress of the disease, it is natural to believe that the offspring from a union of tuberculous individuals would also have a tuberculous tendency, very much as the children of inebriates have a tendency toward inebriety. The consensus of professional opinion, however, says that tuberculosis is not hereditary.

It seems reasonable that the system may be fortified to resist disease by conservative measures, such as the following:

1. Regular, temperate and cleanly habits.
2. Abundant sunshine and fresh air.
3. Good nourishing food.
4. Sufficient rest.

1. *Regular Habits.*—It is essential to observe regular and temperate habits and modes of living. A shiftless vagabond, exposed to the elements, depending on the kindness of charity, or a society rake living in the excesses of overabundance, will be more likely to contract tuberculosis than will active, industrious and sober individuals. Persons afflicted with what are supposed to be incurable diseases sometimes give themselves up to reck-

less riotous revelry in order to drown their troubles. This is a great mistake. The reason is self-evident.

2. *Sunshine and Fresh Air.*—The average individual in our cities gets far too little systematic exercise in the open air during favorable weather. Clerks and shopkeepers are housed from morning until night, year in and year out, in poorly ventilated and stuffy apartments. where the atmosphere is stale and charged with noxious and depressing exhalations from crowds. The majority of the working class shut up in shops, factories, stores and offices are constantly inhaling clouds of germ-laden dust. These individuals furnish a large portion of cases of tuberculosis. Indians have long been known to be susceptible victims of tuberculosis, not because they live in the open, but because of their lives in the dampness of rivers, canoeing, fishing and hunting. This prolonged exposure lowers lung resistance and favors irritation of the bronchial mucous membrane, paving the way for invasion of tubercle bacilli. This should put us on our guard in treating these sufferers. These patients can not very well be treated advantageously who persist in staying at home if the surroundings are damp. A moderately elevated location among the hills where the air is bracing and dry should be chosen for tuberculous patients. The tonic effect of dry ozone to be had among the pine hills and forests aids materially in arresting tubercular lesions. It assists Nature in the reconstructive process; in forming a barrier of fibroconnective tissue around the lesions, in limiting the extension of the destructive process and eventually obliterating it, while a new defensive army of phagocytes encounter the enemy face to face. We can not all live where it is best and most healthful for us, but those especially predisposed to disease should consider the matter of location seriously.

3. *Nourishing Food.*—This is of paramount importance in maintaining bodily strength. Food should be selected which contains the greatest possible amount of nourishment and reconstructive power, and which at the same time agrees with the digestive function of the individual in question. A reasonable amount of food of desirable quality should be selected rather than the greatest quantity for the money. Time should be taken to masticate it thoroughly, thereby avoiding distressing gastrointestinal disturbances. It can not be otherwise than harmful to impose the work of the teeth on the stomach. Gormandizing and gluttony, which often give rise to acute indigestion, should be avoided.

4. *Rest.*—This, too, is an important factor, yet is too often overlooked. The tired and overworked body needs re-energizing by refreshing sleep. Some individuals can get along on much less sleep than others. If one gets, on an average, eight hours' quiet and undisturbed rest each night, and observes the rules of hygiene already mentioned, one's vital powers should be amply reinforced to ward off almost any disease, even tuberculosis.

FOOD-POISONING BY CHICKEN SANDWICHES

D. T. QUIGLEY, M.D.
NORTH PLATTE, NEB.

A few weeks ago eighty-three people gathered at a new barn seven miles north of North Platte at a dance. At 1 o'clock in the morning they were served with a lunch consisting of chicken sandwiches, cake and coffee. The chicken had been prepared the day before by being cooked, cooled and run through a sausage chopper. The weather was very hot and humid. The chopped chicken was kept over twenty-four hours before the sandwiches were made and eaten. The next day, about twenty hours after the supper, fifty-two people who had eaten the lunch were reported sick. Later several more reported, making the whole number about sixty. All who had eaten the chicken were sick, but those who ate cake and coffee and did not eat chicken were not affected. All these patients suffered practically the same symptoms, differing only in degree. They were taken with severe cramps in the bowels, followed by diarrhea and vomiting. Rise of temperature was present in every case that I examined, varying from 101 to 103½. Some were taken sick seven hours after eating the chicken; others were taken sick as late as twenty-four hours after. One man told me that he had taken two big drinks of whisky after the lunch and thought he had escaped any bad effects, but on placing a thermometer under his tongue I found his temperature to be 100.

None of the chicken could be obtained for bacteriologic examination but it is evident that bacterial infection, probably proteus or paratyphoid, was the cause of the poisoning in this case. Proteus as a rule, however, causes little or no fever but does cause severe gastro-intestinal symptoms. Clinically this outbreak resembled infection with the *Bacillus enteritidis* of Gartner. Bollinger states that four-fifths of meat-poisonings are caused by this bacillus but in this case the chickens were stated to have been in good health before being killed. Most cases of poisoning from the Gartner bacillus come from "emergency slaughtering," or where the animal has been killed because of disease.

Professor Dieudonné in his book on food-poisoning states: "Meat poisoning may be occasionally produced by the hay bacillus (*Bacillus subtilis*). An instance of this is reported by Lubenau, who observed an outbreak among the inmates of the Beelitz sanatorium, in 1906. About three-fourths of the 400 inmates and a large part of the help were affected shortly after eating meat croquettes. They had been served at the noon meal; at about 11 in the evening a large number of persons were seized with a profuse diarrhea, persistent vomiting, severe headache and great prostration. In two or three individuals fever was also present. Bacteriologic examination revealed the presence of a bacillus belonging to the hay bacillus group."

I believe it of considerable importance that these cases be reported and that bacteriologic examination be made in every case possible.

GOUTY AFFECTIONS OF THE NERVOUS SYSTEM

REPORT OF AN INTERESTING CASE

W. T. PRIDE, A.M., M.D.
MEMPHIS, TENN.

Formerly the term lithemia was used to cover up our ignorance in regard to a number of affections of uncertain origin. We now know that there is no such disease, but we recognize some of the terms formerly included, of one of which I will report an interesting case.

History.—The patient was a white man, aged 32, married; occupation, telegraph operator. His father and mother were living and well; no history of rheumatism or gout. The patient had had the usual diseases of childhood and typhoid fever ten years before coming under observation. He has had periodic attacks of arthritis of the left knee for the past three years, accompanied by some swelling and tenderness; facial neuralgia for past three years, only slight.

Present Illness.—This began one year before the present attack, with slight headache, constipation, scanty urine and great nervousness. The patient suddenly awoke one night with agonizing pain in the lower right quadrant of the abdomen, nausea and vomiting. The next morning he walked to a physician's office, where two surgeons pronounced his case as one of appendicitis and advised immediate operation. This he refused. He stated that he had no fever, slow pulse, slight tenderness, no rigidity. Recovery was slow. A few months after this he had a second attack similar in every way to the first except that the pain was at the margin of ribs in mid-axillary line. The physicians called pronounced this hepatic abscess. The patient again refused operation and recovery ensued.

Examination.—On June 5, 1909, I found the patient suffering from agonizing pain, confined to the right nephritic region, headache, nausea, vomiting and great nervousness. There was some slight discoloration of the conjunctivæ; pulse was 68; temperature, 98.3; some slight tenderness over point of pain but no radiation. There was no rigidity. The kidney was not palpable; the liver was normal in size. Hot applications failed to relieve pain, and morphin was given. Urine was scanty, highly colored, depositing a heavy sediment on standing; sp. gr. 1028, acid, no albumin or sugar. Microscope gave quantities of mixed urates and uric acid crystals; no pus or blood cells. Blood count was normal. The Garrod string test was not applied.

Treatment.—This consisted in relieving the constipation by means of alkaline diuretics, careful dieting and copious draughts of water. Recovery was rapid and the patient states that he feels better than for the past year.

It will be noted that in no attack did he have fever, rapid pulse, pronounced tenderness or any rigidity; that headache, nausea, vomiting and extreme nervousness accompanied all and that each attack was preceded by constipation, headache and scanty, highly colored urine.

Such cases are interesting, not from their rarity, but from a diagnostic standpoint. We are too prone to consider every abdominal pain as indicative of appendicitis, cholelithiasis or ureteral calculus.

The periodic attacks of arthritis are entirely relieved by the salicylates, alkaline diuretics and hot applications. These attacks are not necessarily coincident with the other affection, but has given him some trouble during the last attack. The facial neuralgia has given the patient no trouble since the first attack of the present trouble.

TUBERCLE BACILLI IN THE BLOOD

ORLANDO H. PETTY, M.D.
AND
A. M. MENDENHALL, M.D.
Pathologist and Resident Pathologist, respectively, St. Timothy's Hospital
PHILADELPHIA

Drs. M. P. Ravenel and Karl W. Smith of Madison report[1] eighteen cases of tuberculous patients whose blood they examined by the Rosenberger method; they failed to demonstrate tubercle bacillus in the blood of a single case, and conclude: "This investigation has been confirmed by reports from all over the world, and the only conclusion that can be reached is that the Rosenberger method is of no value."

We wish to report ten such examinations, a number quite too small to warrant us in criticizing such an authoritative and conservative worker as Rosenberger, yet sufficient, we think, to permit us to question the above results and conclusions.

Case 1.—Clinical diagnosis, pulmonary tuberculosis; bacillary sputum.

Blood examination: Some microscopic fields, no tubercle bacilli; *others* had various numbers, the highest being nineteen in one field.

Case 2.—Patient had hip-joint disease three years before coming under observation, abscess formation; operation, recovery with fixation; *x*-ray shows partial destruction of head of femur and acetabulum. Physical examination and clinical symptoms negative.

Blood examination: Tubercle bacilli as high as nine in field.

Case 3.—Clinical and physical signs of pulmonary tuberculosis; sputum non-bacillary.

Blood examination: As many as 6 bacilli in one field.

Case 4.—A child with hip trouble; *x*-ray negative for osseous destruction. Physical examination negative.

Blood examination: Tubercle bacilli in blood.

Case 5.—A young man, now apparently healthy, although two years before coming under observation he was very much "run down." Afternoon and evening temperature as high as 101 F.; cough and loss of weight. Physical examination at that time and present, negative. Dozens of sputum examinations, also examinations of urine and feces, negative for tubercle bacilli.

Blood examination: As high as 10 tubercle bacilli in a field.

Case 6.—A patient with axillary adenitis. Pathologic report on removed glands, sarcoma.

Blood examination: Negative for tubercle bacilli.

Cases 7 and 8.—Positive findings. A diagnosis of typhoid fever has been made since. One of these cases at least is clinically typhoid. In each of these cases several hours' search revealed only a few bacilli.

Case 9.—This case had a provisional diagnosis of tabes dorsalis with an unexplainable temperature.

Blood examination: Positive for tubercle bacilli.

Case 10.—Pulmonary tuberculosis; bacillary sputum.

Blood examination: Positive.

Our technic is Rosenberger's improvement on what he originally used. The venous blood is smeared rather thickly on cleaned slides, dried, laked in distilled water, fixed, then stained with gently heated carbol fuchsin for five minutes, washed with water, decolorized with 25 per cent. nitric or sulphuric acid, then stained with methylene blue, or with Gabbet's solution used immediately after the carbol fuchsin. There is no doubt but that morphologically and tinctorially these were tubercle bacilli. If this technic does not demonstrate that these were not tubercle bacilli, then one cannot make a positive diagnosis of bacillary sputum without inoculation tests.

We do not wish to go on record as to the practical value of the Rosenberger method, but report our findings to encourage others to continue their labors, for the subject certainly can not be considered a closed one.

---

[1] Proceedings of the State Medical Society of Wisconsin, reported in The Journal A. M. A., Aug. 21, 1909, liii, 649.

New and Nonofficial Remedies

Since the publication of the book "New and Nonofficial Remedies, 1909," the following articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections to aid in the revision of the matter before publication in the book are asked for.

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that so far as known it complies with the rules adopted by the Council.

W. A. PUCKNER, Secretary.

TRANSFER OF AGENCY

Triferrin and Triferrol (see New and Nonofficial Remedies, 1909, p. 134 and 135), formerly sold by C. Bischoff & Co., New York, are now sold by Knoll & Co., New York.

MASSOLIN—Cultura Bacilli Bulgarici-Lederle.—Massolin is a pure culture of the *Bacillus bulgaricus* of Massol, grown on one of the following media: Calcium carbonate lactose broth, calcium carbonate dextrose broth, calcium carbonate Cohendy broth, or Cohendy broth.

The material for one of the above broths is sterilized for thirty minutes on three successive days and then placed in the incubator for at least forty-eight hours to determine its sterility before using. The material is then put into large flasks, inoculated from test tube cultures of the bacillus and incubated at 37 C. (98.5 F.) for from twenty-four to ninety-six hours. It is then tested to see that it is free from contaminating organisms.

The preparation is of an amber color and has the odor and taste of the particular medium employed as its base.

The material should be inoculated into milk and into the above media in test tubes and smeared on Cohendy agar. The cultures should be examined microscopically for the detection of contaminating organisms.

Actions and Uses.—The culture tends to prevent the growth of putrefactive and pathogenic organisms. It is said to be useful in the treatment of suppurative conditions and is said to have been found especially beneficial in atrophic rhinitis, chronic nasal catarrh, inflammations of the frontal sinus, antrum, ethmoidal cells, middle ear, etc.

Dosage.—The culture should be liberally applied directly to the diseased area and in ordinary nose and throat affections the contents of one bottle 7.5 Gm. (¼ ounce) may be employed at each treatment.

Manufactured by Lederle Antitoxin Laboratories, New York (Schieffelin & Co., New York).

No patent or trademark. U. S. Government License No. 17.

CALCIUM LACTATE—Calcii Lactas.—Calcium lactate, Ca $(C_3H_5O_3)_2.5H_2O$, is the calcium salt of lactic acid.

It is prepared in the manufacture of lactic acid by the lactic acid fermentation of sugar or by the neutralization of lactic acid by calcium carbonate.

It occurs in white crystalline masses or powder, odorless and tasteless. It is soluble in 9.5 parts of water, easily soluble in hot water. At 100 C. (212 F.) it loses water of crystallization.

If calcium lactate is heated gently with a mixture of sulphuric acid and potassium permanganate the odor of aldehyde will be given off. An aqueous solution of calcium lactate will throw down a white precipitate, insoluble in water and acetic acid, on the addition of a solution of ammonium oxalate.

Actions and Uses.—Calcium lactate has the pharmacologic action of other calcium salts. Being less irritating than the chloride, it may be given subcutaneously. It is used to increase the coagulability of the blood.

Dosage.—0.5 to 4 Gm. (7 to 60 grains).

TANNISMUTH—Bismuthi Bitannas.—Bitannate of Bismuth. Tannismuth is the bismuth salt of tannic acid in which approximately one atom of bismuth is combined with two molecules of tannic acid having approximately the formula Bi $(OH)(C_{14}H_9O_9)_2$ and containing between 17 and 21 per cent. bismuth.

It is a light yellow powder with slightly astringent taste, insoluble in water, soluble in cold caustic alkalies, and in diluted hydrochloric acid.

Actions and Uses.—It is claimed that one molecule of the acid becomes operative immediately after ingestion, e the other is slowly separated and prolongs the astrin- action throughout the entire length of the alimentary nal.

It is said to be useful in chronic intestinal catarrh, involving different portions of the intestinal tract.

Dosage.—0.3 to 0.6 Gm. (5 to 10 grains) three to five times daily.

Manufactured by Chemische Fabrik von Heyden, Radebeul near Dresden, Germany (The Heyden Chemical Works, New York). German patent No. 172,933. U. S. trademark No. 36,916.

PEROXIDE ZINC SOAP—Sapo cum zinci peroxido.—Peroxide Zinc Soap is a soap containing 10 per cent. zinc peroxide, which see.

Actions and Uses.—It is said to be useful as a vehicle for employing zinc peroxide in the treatment of skin diseases.

Prepared by J. Eavenson & Sons, Camden, N. J., for the Roessler & Hasslacher Chemical Co., New York. U. S. patent No. 787,776. No trademark.

HOMATROPINE HYDROCHLORIDE—Homatropinæ Hydrochloridum.—Homatropine Hydrochloride, $C_{16}H_{21}NO_3HCl$, is the hydrochloride of the alkaloid homatropine, obtained by the condensation of tropine and mandelic acid.

Homatropine hydrochloride occurs as small white crystals, soluble in water and alcohol and melting at 216 to 217 C. (420.8 to 422.6 F.).

If sulphuric acid containing a trace of potassium dichromate be added to a crystal of the salt an evanescent pink color will be produced which rapidly changes to green. If 0.01 Gm. of the salt be added to 5 drops of nitric acid and evaporated to dryness in a porcelain dish the residue should not acquire a violet red color upon the addition of a few drops of alcoholic potassium hydroxide test solution (absence of atropine, hyoscyamine or hyoscine). If 1 c.c. of an aqueous solution of the salt (1 to 100) be made alkaline with ammonia water, shaken out with chloroform and the chloroformic solution evaporated to dryness, the residue should turn yellow and finally brick red when warmed with about 1.5 c.c. of a solution of 1 part mercuric chloride in 30 parts of a mixture of 5 volumes alcohol and 3 of water. (absence of most other alkaloids except atropine and hyoscyamine). If to an aqueous solution containing 0.1 gm. of the salt an excess of potassium hydroxide test solution be added, liquid extracted with ether and the latter evaporated spontaneously, the crystals which form should melt at 96 C. (204.8 F.).

Actions and Uses.—Homatropine is less poisonous than atropine, but the same symptoms are produced by it when exhibited in large doses.

The hydrochloride is used as a mydriatic in ophthalmic surgery. The mydriatic effect begins in ¼ to ½ hour and reaches a maximum in one hour and disappears in 36 to 48 hours. Accommodation paresis ceases earlier.

Homatropine hydrochloride is given for the same indications as the hydrobromide, but has no advantage over the latter.

Dosage.—It is applied to the eye in 1 per cent. solution.

THEPHORIN—Theobrominæ Sodio-Formas. — Theobromine Sodium Formate. Thephorin $C_7H_7N_4O_2Na+NaCHO_2,+H_2O$ is a double salt of sodium formate and theobromine sodium.

It is prepared by dissolving 70.1 parts of theobromine sodium in 200 parts of water and adding to it a solution of 23.5 parts of anhydrous sodium formate in 50 parts of water, filtering the mixture, and evaporating to dryness on a steam bath or in vacuo. Thephorin is a white, odorless powder having a saline bitter taste and is readily soluble in water producing an alkaline solution. From its aqueous solution the theobromine is precipitated by acetic acid. In the filtrate formic acid is indicated by the reduction of silver nitrate.

If an aqueous solution of thephorin be faintly acidulated with nitric acid, the filtrate should give no precipitate with barium chloride, nor with silver nitrate, nor with ammonia water and hydrogen sulphide.

Two Gm. thephorin are placed in a porclain dish and dissolved in 10 c.c. water with the aid of gentle heat. A few drops of phenolphthalein test solution are placed in the solution, neutralized with nitric acid, the faint alkaline reaction is again restored by means of diluted ammonia, the solution is then thoroughly stirred and, with frequent stirring, allowed to stand for three hours at ordinary temperature.

The resulting precipitate collected on a weighed filter of 8 cm. diameter, is dried at a temperature of 100 C.; it is then washed twice with cold water using 10 c.c. each time. The filter is again dried at a temperature of 100 C. and weighed. The weight of the precipitate should amount to 1.2 gm.

Actions and Uses.—Thephorin is said not to irritate the stomach and acts as a powerful diuretic, both on account of the theobromine which it contains and also from the action of sodium formate.

It is said to be useful in cardiac affections, nephritis, dropsy, etc.

Dosage.—0.5 Gm. (7½ grains) two or three times a day in the form of powder or as tablets.

Manufactured by F. Hoffmann-LaRoche & Co., Basel, Switzerland (The Hoffmann-LaRoche Chemical Works, New York). U. S. patent No. 172,932. U. S. trademark No. 59,581.

Thephorin Tablets, 7 1/2 grains: Each tablet contains thephorin 0.5 gm. (7½ grains).

BENZOSALIN—Methylis Benzoyl-Salicylas. — Benzoyl-Salicylic-Acid-Methylester—Methyl Benzoyl-Salicylate. Benzosalin, $C_6H_4.O(CH_3).COO(C_6H_5CO)$, 1:2 $= C_{15}H_{12}O_4$ is the methylester of benzoyl salicylic acid.

Benzosalin is prepared by a reaction between the methylester of salicylic acid and benzoyl chloride in the presence of sodium hydroxide. The resulting product is washed with water and after drying is crystallized out from alcohol.

Benzosalin consists of fine, white crystals with a very faint aromatic odor. It melts at about 85 C. (185 F.). It burns leaving no residue. It dissolves readily in chloroform, benzene and in 35 parts of 90 per cent. cold alcohol, also in pure concentrated sulphuric acid.

Actions and Uses.—Benzosalin is said to pass the stomach unchanged and to be decomposed into its constituents, benzoic and salicylic acid in the intestines. It is said to be free from the undesirable by-effects of salicylic acid. It is claimed that benzosalin is an intestinal antiseptic.

Benzosalin is said to be useful in rheumatic affections, such as arthritis, neuralgia, sciatica and migraine, and in arthritis deformans.

Dosage.—0.5 to 1 Gm. (7½ to 15 grains). Daily dose 3 to 4 Gm. (45 to 60 grains) in powder or tablets.

Manufactured by F. Hoffmann-La Roche & Co., Basel, Switzerland. (The Hoffmann-La Roche Chemical Works, New York.) U. S. patent No. 799,706. U. S. trademark No. 58,757.

Benzosalin Tablets, 5 grains: Each tablet contains benzosalin 0.3 Gm. (5 grains).

FERROUS LACTATE—Ferri Lactas.—Iron Lactate—Ferrum Laticum. (U. S. P., 1890; Pharm. Germ., edit. 4; Pharm. Helvetica, edit. 4; Pharm. Belgica, edit. 3; Pharm. Francaise, 1908); Ferrous lactate, Fe $(C_3H_5O_3)_2+3H_2O$ is the ferrous salt of lactic acid.

Ferrous lactate occurs in pale greenish-white crusts, consisting of small, needle-shaped crystals, or transparent green scales, having a slight, peculiar odor and a sweetish, ferruginous taste. It is slowly soluble in about 40 parts of cold, and in 12 parts of boiling water; almost insoluble in alcohol; freely soluble in a solution of an alkali citrate yielding a green solution.

When strongly heated, the salt froths, gives out dense, white, acid fumes, chars and finally leaves a brownish red residue.

The aqueous solution of the salt has a *greenish-yellow* color, a slightly acid reaction, and gives a deep blue precipitate with potassium ferricyanide, and a light blue one with potassium ferrocyanide.

A 2 per cent. aqueous solution of the salt should not yield more than a faint opalescence with a solution of lead acetate (limit or absence of sulphate, chloride, citrate, tartrate and malate). The aqueous solution after acidulation with hydrochloric acid should not yield any precipitate or coloration when treated with hydrogen sulphide (absence of foreign metals).

The aqueous solution, acidulated with nitric acid, should not afford more than a slight opalescence with barium chloride solution or with silver nitrate solution (limit of sulphate or chloride). If 25 c.c. of a 2 per cent. aqueous solution of the salt be mixed with 5 c.c. of diluted sulphuric acid, the mixture boiled for a few minutes, an excess of sodium hydroxide added and the mixture filtered, the filtrate when mixed with a few drops of alkaline cupric tartrate solution and boiled, should not yield a red precipitate (absence of sugar).

If a portion of the salt be triturated with strong sulphuric acid, no offensive odor should be developed (absence of butyric acid), nor should any gas be evolved (absence of carbonate), and the mixture after standing for some time should not assume a brown color (absence of sugar, gum, or other readily carbonizable impurities).

If 1 gm. of the salt, contained in a porcelain crucible, be moistened with nitric acid and carefully ignited, it should leave a residue of ferric oxide weighing not less than 0.270 nor more than 0.278 Gm. This residue should not have an alkaline reaction on litmus paper, nor yield anything soluble to water (absence of foreign salts).

Actions and Uses.—Ferrous lactate is a mild chalybeate which because of its feeble taste may be taken without difficulty.

Dosage.—0.08 to 1.3 Gm. (1 to 20 grains). Owing to its liability to oxidation, it is best prescribed in solutions containing much sugar. Syrup dissolves 1 Gm. in 120 Gm. (4 grains to the fluidounce).

**DIGALEN—*Liquor Digitoxini Solubilis.*—*Digalen is a mixture said to contain 1 part of Digitoxinum Solubile Cloetta,[1] in 1,000 parts of glycerin and 1,600 parts of distilled water with 7.5 per cent. of alcohol. 1 Cc. is said to contain 0.0003 Gm. of Digitoxinum Solubile Cloetta.

Digitoxinum solubile Cloetta is manufactured as follows:

The dried and finely powdered leaves of digitalis are extracted with dilute alcohol: then the extract is mixed with lead acetate *solution in order to remove chlorophyll and resins and filtered.* From this filtrate the excess of lead is precipitated with sodium sulphate and the alcohol distilled off in vacuo. From the remaining aqueous solution the substance is extracted by ethereal solvents and precipitated afterwards in an amorphous and pure condition according to a special secret method.

Digalen is a colorless or slightly yellowish fluid of an agreeable aromatic smell and a sweet taste which turns bitter afterwards.

Digitoxinum Solubile Cloetta is described as an amorphous, white or slightly yellow powder. Its solubility is said to be about five times as great as that of crystallized digitoxin. It dissolves very readily in alcohol and choloform and a little less readily in ether. It has an intensely bitter taste and causes violent sneezing. It is claimed to be the form in which digitoxin exists in the digitalis leaf before it is deposited in a crystalline and insoluble form.

In order to test for the active principle in digalen a few drops of dilute acetic acid are added to 2 c.c. of digalen solution and then the mixture is shaken out with chloroform. This solution is evaporated and the residue dissolved in about 2 c.c. of glacial acetic acid containing traces of iron chloride. If to this solution concentrated sulphuric acid is added cautiously without mixing, so as to form a separate layer at the bottom of the test tube, a small brown ring will form first between the two layers which becomes broader in the course of some hours and expands towards the top of the tube in a blue green to black shade and towards the bottom of it in a reddish brown one, while the acetic acid acquires finally a dark green-blue color.

The amorphous character of the digitoxin contained in digalen is proved by the following tests: Dissolve 4½ mg. digitoxin amorphous (the entire content of digitoxin amorphous of an original vial of digalen) in 0.225 c.c. of 96 per cent. alcohol. Place the same quantity, 4½ mg. of crystallized digitoxin, also in 0.225 c.c. alcohol 98 per cent.

The amorphous digitoxin dissolves readily to form an entirely clear solution. The crystallized digitoxin, however, dissolves slowly and incompletely. This solubility difference is still more marked if diluted alcohol is employed.

A drop of the clear filtered alcoholic solution of amorphous digitoxin leaves no crystallin residue on evaporation, but a solution of crystallin digitoxin shows on evaporation an active separation of minute, sharp and distinctly formed crystals arising especially on the edge of the drop.

Actions and Uses.—The same as Digitoxin.

(See Jour. A. M. A., May 8, 1909, p. 1499.)

Dosage.—Average single dose 1 Cc. (16 min.) Maximum single dose 2 Cc. (32 min.), maximum daily dose 6 Cc. (96 min.) Intravenous injections of 1 Cc. (16 min.) may be repeated at intervals of one-half to one hour as necessary. For protracted dosage from 1 to 2 doses daily of from 7 to 14 drops are given.

Manufactured by F. Hoffmann-LaRoche & Co., Basle, Switzerland. (The Hoffmann-LaRoche Chemical Works, New York.) U. S. trademark No. 43,593.

Therapeutics

CHRONIC NEPHRITIS

Chronic interstitial nephritis, Bright's disease, or better named under the clumsy but more descriptive title of cardiovascular-renal disease, is markedly on the increase in this country; consequently, it is necessary for the medical profession to take means of preventing its occurrence. It is unimportant for the discussion of its prevention which part of the anatomy of the individual patient has farthest advanced in the pathologic process. One patient may have arteriosclerosis greatest in evidence, another cardiac weakening, another renal disturbances, but the disease in any case is the same. Increased blood tension seems to be the premonitory condition and the forerunner of all subsequent disturbances in this cardiovascular-renal disease.

A question that has been considerably discussed is: What is the etiology of this increased blood tension? The condition has been variously attributed to tension caused by increased nervous activity; to hypertrophy of the left ventricle, which, however, is probably generally compensatory to overcome the increased arterial pressure; to the circulation in the blood of toxins absorbed from the intestines, which irritate the vessel walls and the central nervous system; to toxins retained in the blood from insufficient excretion by the kidneys; and to a hypersecretion of the vasoconstrictor element of the suprarenals, or to a relatively increased secretion from these glands, at a period of life (after fifty) when the thyroid furnishes a diminished secretion and therefore less vasodilator stuff. It is probable that all or several of these elements, which cause arterial irritation, are at work at once, and there probably is no one cause for a slowly developing endarteritis, increased blood pressure, and a future arteriosclerosis. The parts that chronic lead poisoning, syphilis and its treatment with mercury, serious acute infections, prolonged serious illness, alcohol and the ever frequent over-use of tobacco have played in causing the signs of beginning sclerosis must all be taken into consideration, when the attempt is made to prevent the development of, or to stay, the pathologic process.

It is manifestly impossible to prevent the serious conditions that have gone before, viz., acute illness, syphilis, mercury and lead. It is possible to prevent the continuation of causes that are continuously acting in the individual patient, such as alcohol, tobacco, over-eating, intestinal indigestion, and the nervous tension caused by an excessive amount of mental labor, or by the strenuous life that the patient may be leading.

In this insidious, creeping and almost sneaking disease it is obviously important to recognize early its premonitory symptoms and signs. Not infrequently it is the oculist who is consulted for disturbances of vision, who first notes arterial changes in the retina. The symptoms which the patient has and which he may take note of, or, on the other hand, take no notice of, are: a slight tendency, or an increased tendency, to headache; slight headaches on first awakening in the morning; some early muscle debility in the morning, which soon passes away, as does the headache; at times, some pain in the occipital region; occasionally intermittency of the heart, sometimes an increased force of the beat, especially on first lying down; sometimes slight attacks of palpitation and dyspnea after exertion that should not cause cardiac disturbance; at times, on exertion, a peculiar paleness about the mouth; at other times flushing of the face; slight puffiness of the ankles at night, not real edema; a sensitiveness of the skin to slight irritation, so that rubbing or scratching causes an intense local hyperemia that may persist for some minutes; at times occasional digestive disturbances, nausea and vomiting attacks; frequently a coated tongue and a bad taste in the mouth in the morning; possibly a little diarrhea without adequate food, cold, or inflammatory excuse; days of increased frequency of urination; and the tendency to be awakened once, perhaps twice, at night to urinate. These symptoms may bring the patient to the physician, but often do not. In some instances it is the increased frequency of urination at night, or an irritability of the bladder, or a general weakening of the patient from circulatory debility, or actual cardiac distress with possibly slight anginal attacks, that cause the patient to consult his physician.

---

[1] The Council has not determined whether digalen contains "soluble amorphous digitoxin" or not, but accepts it merely as a standardized soluble and fairly stable digitalis preparation.

Besides the above symptoms, the physician finds either increased pulse tension, or, in many instances, a pulse tension that was increased has become lowered from slight cardiac weakness, before the patient has consulted him. In all cases, the blood pressure should be taken and noted, and circulatory treatment directed according to the reading. The physician will often find an intermittency, sometimes an irregularity, of the heart, often slight enlargement, and at times a soft systolic blow at the apex, showing weakness and a slight dilatation of the left ventricle. If there is a systolic blow at the aorta, there may be a slight roughening of this valve, or the sound may be of hemic origin, even if the patient is not anemic; in other words, either one of these cardiac murmurs, the aortic or the mitral, may disappear under proper treatment.

The physician may note an abnormal tendency of the veins of pendent portions of the body (especially of the hands when hanging down) to become dilated, showing some circulatory insufficiency. This may be due to slight arteriosclerosis, or it may be due to cardiac weakness.

The tongue may show varying signs of digestive disturbances or an irregular, patchy, coated condition which is typical of renal insufficiency.

The urine may be of low specific gravity, may contain a trace of albumin, and may show hyaline and granular casts, but all these important urinary findings may be absent. It is essential to examine several specimens of the twenty-four hours' urine to determine the ability of the kidneys to excrete not only nitrogen, but salts. The results of these examinations will decide the modifications of the diet that are necessary.

The results of the examination of the circulation will determine the amount of rest that is necessary, or the amount of exercise that should be allowed.

Drs. N. E. Ditman and W. H. Welker, New York, in a series of articles in recent numbers of the *New York Medical Journal*, ending June 5, 1909, have scientifically presented the symptoms, etiology and treatment of nephritis. They make the statement that in a large proportion of instances this disease is preventable, and certainly ordinarily in its incipiency it may be stopped or stayed. If the patient comes to the physician when the above symptoms only are present, prophylactic measures to prevent the further development and progress of the disease are presented as follows by Ditman and Welker:

Alcohol.—The pernicious effects of alcohol in causing nephritis is attributed generally to its interference with oxidation, and imperfect oxidation is considered by these experimenters to be a distinct cause of nephritis. Consequently, as has long been theoretically known, patients with early signs of cardiovascular-renal disease must not take alcohol in any form.

Cold.—The climate of the temperate zone is more conducive to the development of nephritis than are zones where it is colder and zones where it is warmer. The rapid variations in temperature experienced in temperate climates cause marked changes in the tone of peripheral vessels. Sudden cold raises the blood pressure, inhibits excretion by the skin, and puts more work on the kidneys. For this reason the patient with a beginning chronic nephritis should live during the colder and variable seasons of the year in a warmer climate, if he has the money ability. If he has not the financial means to change his abode, he should be so clothed as to prevent the surface of his body from becoming chilled. Ditman and Welker believe these sudden changes of temperature from warm to cold interfere with oxidation, and for this reason cause kidney irritation.

Exercise and Baths.—The authors believe that exercise for those who devote most of their time to business and its worries, or household duties and frets, and who eat hurriedly, is essential for proper oxidation and, therefore, should enter into the prophylactic treatment of nephritis. Outdoor exercise, plenty of sunlight and sun baths, especially when applied to the whole body, are of great benefit to the patient who is on the verge of arteriosclerosis, chronic nephritis, and their associated conditions. For some patients frequent warm baths and Turkish baths are indicated. This is especially true for the patient who is over-weight, and for the patient whose skin does not normally perspire and therefore does not normally excrete. If the heart is impaired, Turkish baths should not be taken.

Food.—Over-eating of protein nutriment is certainly a promoter of the causes of arteriosclerosis and chronic nephritis. This is especially true if the intestinal digestion is imperfect. Meat, especially, is the protein that is most likely to produce toxins, if maldigested, and if putrefaction occurs in the intestines. Therefore, a patient, who is on the verge of or has a beginning, chronic nephritis, should eat meat but once a day, and that in not large amount. It may be well to take meat out of the diet for a short period, at least. Raw meats, raw oysters, and especially the proteins that contain large amounts of nuclein, as liver and pancreas, should be eliminated from the diet. Meat broths and meat soups that contain a large amount of extractives should be avoided.

Intestinal Putrefaction.—While it is probably not true that if the colon of the human being after forty could be removed he would live to be a hundred, more or less, it certainly is true that intestinal putrefaction, whether mostly in the colon or more or less in the small intestine, is conducive to the absorption of toxins that are irritant not only to the arterial walls, but specifically to the kidneys, and such irritants have been found to promote albuminuria and chronic interstitial nephritis. Any food, diet, regulation of habits, physical or medicinal treatment that will prevent or inhibit intestinal putrefaction will promote the prophylaxis of chronic nephritis.

The primary treatment of this condition is catharsis, followed by such laxative treatment as will keep the intestinal contents normally moving. Radical changes in diet will change the pabulum which aids the growth of the obnoxious bacteria.

Artificially soured milk seems to be a successful treatment of many cases of intestinal putrefaction. Yeast is another valuable treatment of this condition. The so-called intestinal antiseptics are of some advantage and sometimes are curative.

The prevention of the condition, or the prevention of its recurrence after it has been stopped, should begin with proper filling, or extracting, decayed teeth, and frequent and repeated cleansing of the teeth, mouth and throat with such mildly antiseptic or alkaline gargles as are deemed advisable, and the limitation of the food to such articles as are easily and well digested by the particular patient. Foods that tend to carry bacteria and that promote putrefaction should be prohibited, and Herter especially prohibits cheese and the skins of fruit.

Dilute hydrochloric acid is a valuable treatment, if indicated.

Ditman and Welker believe that quantitative determination of the creatinin eliminated will denote the condition of the digestion and the amount of maldigestion and suboxidation, and therefore the likelihood of the development of nephritis.

TREATMENT OF NEPHRITIS WHEN ACTUALLY PRESENT

The above suggestions for prophylactic measures should all be enforced, and Ditman and Welker emphasize the fact that all the methods of treatment, physical and medicinal, found of advantage in chronic nephritis and uremic conditions, are those that tend to promote oxidation in the body.

They have investigated the indican and creatinin excretion in reference to the presence of such symptoms as high tension, headache, lassitude, nausea and vomiting, edema and dyspnea, and find that the arterial tension seems to be increased when there are large amounts of indican in the urine and when the excretion of creatinin is reduced. Also the greater the amount of indican the more the headache, and the less creatinin excreted the more the lassitude, nausea and vomiting. Dyspnea and edema seem to have no relation to the indican or creatinin.

Patients with chronic interstitial nephritis do not excrete sodium chlorid well, and this retention seems to cause edema; hence if there is edema in chronic nephritis the sodium chlorid intake should be reduced, or it should be entirely withheld for a time. Albuminuria is also decreased, when present, by a saltless diet.

The diet in chronic nephritis should be carefully considered. An absolute milk diet is inadvisable. A large amount of water is inadvisable. The amount of meat allowed depends on the ability of the kidneys to excrete nitrogen. There is no difference in the extractives or in the ability of the kidneys to excrete the extractives of ingested red or white meat. The main object in the diet of the nephritic is that he should have a little of all the elements that are necessary for nutrition, nothing that causes indigestion or serious constipation, nothing that has been found by chemical analysis of the urine to be difficult of excretion by the kidneys, and enough food to keep the weight as near normal as possible. He may therefore have some milk, if it agrees; water sufficient to keep the excretions normal, but not sufficient to cause edema, nor in large amounts, if the arterial tension is high, or if he has arteriosclerosis; meat in small amount once a day; eggs; oatmeal, or other cereal; bread, potatoes and other fresh vegetables (no canned food); non-irritating, preferably cooked, fruits; all depending entirely on his ability to digest properly and to excrete the end-products of each particular food. As uric acid is not ordinarily well excreted by kidneys which are in the condition of interstitial nephritis, the purin bases and all such foods as contain large amounts of nuclein should be prohibited, typically liver. Also, all spices and often tea and coffee should be withheld from the diet.

The care of the skin in the nephritic is of special importance. Proper exercise should be taken to cause normal perspiration; warm baths and massage promote normal excretion by the skin. If the skin is a normally excreting organ in the patient who has chronic nephritis he may do well for years. If the skin is dry, diseased and does not properly excrete, he will soon have uremic symptoms.

No drug of any kind that causes irritation of the kidneys during its excretion should be administered to a patient with chronic nephritis.. Such drugs are all of the coal-tar products, some of the vasoconstrictors, the stimulant and irritating diuretics, the aromatic oils, and many of the synthetic compounds.

As most nephritic patients are, or soon become anemic, iron in some simple form should be administered, and there is no better iron for this purpose than the tincture of the chlorid, in from 1 to 5 drop doses, in a little fresh lemonade, administered two or three times a day.

It has been shown that the alkalinity of the blood is diminished in patients who are suffering from chronic nephritis. Consequently, the alkalies seem indicated and have long been found of some advantage to these patients. Alkalies are also promoters of oxidation. It should not be forgotten, however, that if they are long administered they may promote tissue waste and therefore loss of weight. While also they are diuretics, diuretics are not always indicated in nephritis, even when the amount of urine passed is small, as injured kidneys do not need stimulation of any kind, but rather derivation such as would be produced by cathartics and by hot baths. Also, urine that is abnormal in its constituency tends easily to have its normal acidity reduced and become neutral or even alkaline, in which conditions bacteria grow and infectious disturbances start, and slight inflammation from infection can occur in any part of the urinary passages. In this condition alkalies would promote and not diminish the growth of bacteria, hence would be contraindicated.

Colon irrigations, to wash out fecal débris and cleanse the large intestine of bacteria, are especially indicated when there are any symptoms showing that uremia may be imminent. When the symptoms show that the patient is about to have an uremic attack, purgatives, hot baths, colon washings, almost total abstinence from food for twenty-four hours, the administration of water, or a small amount of milk and water only, and absolute rest in bed is the best possible preventive treatment.

INFANT MORTALITY

Probably nothing is more fatal to real progress than a mistaken idea that such progress has already been accomplished. Such assumptions are too common. For instance, there is a very general impression that in the past twenty-five years we have greatly reduced the death rate among infants. Such statistics as are available, however, apparently indicate that whatever advance has been made in lessening infant mortality is due chiefly to the improvement in general living conditions. Dr. Stowell,[1] visiting physician to the New York City Children's Hospital and Schools, in a review of mortality tables for recent years, presents some facts that are rather startling, considering the usual impressions as to our great advance in the prophylaxis of infants' diseases.

The death rate of infants under one year per thousand living, as given by Dr. Stowell, shows very little change in the last thirty years in nearly all the civilized countries. In England, for instance, during the five years from 1876 to 1880, the death rate at this age was 145 per thousand. In the decade from 1893 to 1902 it was 152 per thousand living. In France the figures for the two corresponding periods are 163 and 158; in Prussia, 205 and 199; in Italy, 249 and 173; in Switzerland, 189 and 145, and in the United States, 166 and 165.4. The only country that shows a material reduction in the death rate at this age (and perhaps the last one from which it would be expected) is Italy. There is a good reduction in Switzerland, but that has been made in the last few years, as the death rate under one year in 1895 was higher than that in 1876. In the United States the census figures on this subject are very interesting. The deaths of infants under one year are calculated per thousand deaths in the United States. They run as follows: In 1860, 207; in 1870, 209; in 1880, 231; in 1890, 234; in 1900, 191; in 1906, 202; in 1907, 190. This is, of course, for the registration area, which comprises about one-half of the population of the United States and 90 per cent. of all the population in cities over 8,000.

In spite of all that we have hoped to accomplish by scientific infant-feeding, the mortality records do not support the claim of great advance in the preservation of very young children. From a study of the institutions around New York Dr. Stowell shows that the most important factor in preserving the lives of children is breast-feeding. Children who are fed from the breast have four times the chance of life that orphans or foundlings have.

After this, the most important factor making against infant mortality is the training of mothers in the care for their children and the devotion of the mother to her child. An example of how much this latter factor means for the child is cited from the effect of our Civil War on infant mortality in England. During the war cotton was not shipped from this country to England in the usual quantities. As a result many factories in which mothers worked were closed and the latter had perforce to remain at home and care for their children. This caused a great falling off in infant mortality in the manufacturing cities, in which the death rate of infants is now ordinarily very high.

In France the "consultations des nourrissons," organized in the early nineties, have been found the most effective means of combating infant mortality. Poor mothers bring their babies to the infant consultations each week and are taught how to care for them. Thus the children's illnesses come under observation early. Breast-feeding has increased greatly since the consultations became general, and it has been found cheaper, as well as more effective, to give subsidies for breast-feeding than to furnish pure milk. Over sixty per cent. of the mothers were nursing their children in 1900, but in five years this percentage has increased to more than eighty-one.

The Huddersfield experiment is another instance of the good results of care of the children and encouragement to the mothers. In 1904 the mayor of Huddersfield, England, offered a prize of one pound for every child born during his mayoralty and produced alive and well at the town hall on the expiration of a year from date of birth. A visitor was sent out to note the condition of the children weekly in the meantime; and the infant mortality of Huddersfield for 1904-1905 was reduced from 134 to 54 in the thousand.

Of course the value of these two factors, mothers' milk and mothers' care, has long been recognized; and, by the way, it is rather interesting to observe that two centuries ago the same causes conspired against the welfare of the hapless children of fashionable mothers as to-day. Dr. Stowell quotes Dr. Harris, a physician to William and Mary in the early part of the eighteenth century, who wrote as follows: "It is grievously to be lamented that so many Mothers not only of the high Rank but even of the common Sort can with so much Inhumanity and mere Brutish cruelty desert their tender Offspring and expose them to so many Dangers of mercenary Nurses who are greedy only of the profuse Rewards bestowed on them at Christening and so being weary of their present Employment perform it negligently while they are looking out for a new Prey. Let us make a Survey of the Advantages that permit Mothers so commonly to sacrifice their beloved Offspring. They are the more free Enjoyment of Diversions, the greater Niceness of adorning their Persons, the opportunity of receiving impertinent visits and returning those insipid Favors, the more frequent Attendance on the Theatre or of spending the greater part of the Night at their beloved Cards." And this two full centuries ago! To-day, unfortunately, the family physician must sometimes share the blame for the fact that the child is early deprived of its best chance of life.

---

[1] Med. Rec., May 22, 1909.

The question of reducing the death rate among infants, then, is much more a matter of hygiene and care for the children and proper instruction for the mothers than of rules and proportions of artificial food ingredients and special mixtures. Surely this lesson deserves to be emphasized; and therefore nothing can be more opportune than Dr. Ostheimer's article[1] in a recent issue of THE JOURNAL, urging that physicians use every effort to help the mother to nurse her child. As Dr. Gengenbach remarked, in discussing this article, "every day, every week, every month, that the child receives breast-milk, increases its resistance in the battle for existence which no other feeding method makes possible." To advise the premature weaning of the child without exhausting every means to improve the hygiene of the mother and the quantity and quality of the breast-milk is to become an accomplice of that "Inhumanity and mere Brutish cruelty" of which our colleague of the eighteenth century so justly complained.

COOK AND THE NORTH POLE

After centuries of vain striving, in which scores of expeditions have failed and hundreds of lives been lost, it is a remarkable coincidence that within one week the civilized world should have been electrified by news that the north pole had been discovered independently by two explorers, using different routes. The lure of the pole has never been wholly explainable by the hope of the discovery of valuable lands or scientific data of great practical importance, but there are very few persons who fail to appreciate the ambition of explorers. Men love to go where it is thought that human foot has never trod before, and it is human nature to view the inaccessible as a most important goal. As, little by little, most of the globe has been traversed, explored and added to the maps, the icy wastes of the North have called more and more loudly to be conquered. That the news of the discovery of the north pole came first from a physician gives the medical profession particular interest in this subject, which has filled the newspapers for days past.

DR. FREDERICK A. COOK
Reproduced from "To the Top of the Continent" by permission of Doubleday, Page & Co.

Dr. Frederick A. Cook of Brooklyn is a native American, born in Sullivan County, New York, June 10, 1865. After attending public schools in Brooklyn and graduating from the University of the City of New York, he took his medical course at the College of Physicians and Surgeons of Columbia University, New York, and practiced in Brooklyn for a brief period. His interest early turned to scientific exploration, and he became surgeon of the Peary expedition in 1891. Subsequently his time has been devoted largely to exploration work. He was surgeon of the Belgian Antarctic Expedition, in which he conducted himself with so much credit that he was honored by medals from the Royal Society of Belgium and the Royal Geographical Society of Belgium and was decorated with the Order of Leopold by the king. Another exploit was the ascent of Mount McKinley in Alaska, in which he was the pioneer, in 1906. His writings have been read with great interest. "Through the First Antarctic Night" described his trip with the Belgian expedition; "To the Top of Mount McKinley" described his thrilling ascent of that mountain.

The present expedition was without the elaborate preparations customary for those who have sought the pole. In the final dash, which, contrary to the usual plan of explorers, was made in the winter, Dr. Cook reduced his equipment to the minimum to facilitate speed, and took with him only two Eskimos. Furthermore, he slipped away from this country without heralding his goal. So, as his return startled the world, he meets a demand for proof of his success, a demand which he, of course, expected and a demand which is

Furthermore, he slipped away from this country without heralding his goal. So, as his return startled the world, he meets a demand for proof of his success, a demand which he, of course, expected and a demand which is natural under the circumstances. It does not seem to us to be within our province to decide without reservation that he reached the pole. If a cure for cancer were announced we would feel that the layman who accepted it on newspaper report was a little premature. The examination of Cook's records and data and the placing of the seal of approval on his achievements belong to the scientists who are competent to judge in such matters. We wish Dr. Cook a prompt and enthusiastic acceptance by the authorities whose word has weight.

The medical profession is proud of Dr. Cook, thrilled by his invincible spirit for the conquest of a baffling goal and deeply appreciative of the honor which he has conferred on our calling. This spirit of attacking a difficult problem which has baffled many men is the spirit the medical profession loves to uphold as its ideal. With a far different method but often with the same feeling, the scientist searches for the cause of disease and for its cure. We congratulate Dr. Cook and wish him a speedy return to his native shores and to his wife and children who have so bravely and patiently borne his long absence.

THE LOCALIZATION OF CARCINOMA IN EARLY LIFE

Carcinoma in persons under thirty is uncommon enough to cause comment, and under twenty it is a rare curiosity, but there is no absolute limit below which carcinoma may not appear, as it has been observed even in the first few months of life. There seems to be a striking difference between different tissues in regard to the early appearance of carcinoma, as is brought out by Lindemann[1] in a compilation of the literature on this subject. Carcinoma of the skin seldom occurs in the young, scarcely 1 per cent. of some six hundred cases of cancer of the skin and lip being in individuals under thirty, and but about 2 per cent. of breast cancers under this age. In a large series of cases of carcinoma of the stomach, persons under thirty were the victims in from 2 to 3 per cent., and Riegel has recorded two cases of gastric carcinoma in the new-born, and one in an infant of six weeks. Esophageal cancer seems to be almost unknown before the thirtieth year, and extremely rare before forty; and the generative organs seldom become cancerous in youth, although there are reported cases of a carcinoma of the testicle in a child of one and one-half years, an ovarian carcinoma at nine months, and cancer of the uterus in an eight-year-old child. Three cases of carcinoma of the pancreas between the seventh month and the fourteenth year are also mentioned.

On the other hand certain organs show a relatively large proportion of the cancers which affect them occurring in early life, this being especially true of the kidney and lungs. More than one-third of the cases of renal cancer occur before the tenth year, 5 per cent. each in the second and third decennium, and 10 per cent. between thirty and forty; therefore, over half the cases of cancer of the kidney appear in the years when cancer seldom affects the more common sites of this disease. The lungs, a rare site of primary cancer at any age, show that a strikingly large proportion of such cancers develop in the young; thus of eighty-two cases twenty were in persons between 20 and 30, and in eighteen cases the age was between 30 and 40, so that over a third of these tumors appeared during the period of life when persons are supposed to be immune to carcinoma.

Another unusual site of primary carcinoma is the liver, and here, too, a relatively large proportion of the cases occur in the young, and there is at least one case of carcinoma of the liver in the new-born. Carcinoma of the intestines appears rather frequently in the young, it having been estimated that of all the cases of primary intestinal carcinoma one-sixth manifest themselves before the thirtieth year, and one-seventh between the thirtieth and fortieth years, while no fewer than twenty-three authentic cases before the twentieth year were collected from the literature by Lindemann. No explanation is advanced for this peculiar tendency of tissues which seldom become cancerous at any age, to develop cancers particularly in the young.

CULTIVATION OF THE SPIROCHÆTA PALLIDA

Since Schaudinn several years ago discovered the *Spirochæta pallida,* many attempts have been made to grow the organism on artificial media, but only recently has any degree of success been obtained. Schereschewsky[1] observed multiplication of the spirochete in pure horse serum. This medium heated to 58 or 60° C. for an hour or more becomes gelatinous, though it remains perfectly clear. Material obtained from a syphilitic papule or condyloma is immersed in this fluid and placed under strict anaërobic conditions in the incubator. After a number of days the culture is examined and by both the staining method and dark-ground illumination a notable increase in the number of organisms is seen. He recommends the dark-ground illuminator as very satisfactory and easily recognizes the *Spirochæta pallida* by this method. In a more recent paper[2] he gives the results of more extensive studies. In the first culture shortly after inoculation he noted a large number of the refringens type, but in subcultures and in the old original cultures the pallida form prevails.

In Schereschewsky's cultures the syphilitic organisms occurred in mixed culture with other bacteria. Mühlens[3] announces, however, that he has obtained pure cultures of the *Spirochæta pallida* from a syphilitic gland. He used the method employed by him several years ago[4] in obtaining pure cultures of *Spirochæta dentium.* A tube of horse-serum agar (1:3) is inoculated with the syphilitic material and under strict anaërobic conditions after several days very tiny colonies develop on the agar

which, by breaking the tube, can be isolated and examined. In the fourth generation he obtained pure cultures and morphologically in living and stained specimens they were identical with the original.

Animal experiments using pure cultures are now being carried on by Mühlens, the results of which will soon be reported. Schereschewsky reports negative results thus far on animals. Successful animal inoculations with subsequent recovery of the organism are highly essential and necessary to complete the chain of evidence in establishing the etiologic relation of the spirochete to the disease. Koch's requisites will then be fulfilled as regards syphilis.

Pure cultures of the spirochete will be of great importance in the further study of the disease, opening up new fields especially along the line of immunology and serotherapy. It will place the etiology and pathology on a substantial basis and afford more rational methods for studying and combating the disease.

POSSIBILITIES OF MODERN PREVENTIVE MEDICINE

It has been asserted that if the knowledge of the transmission of disease which we already possess could be fully utilized it would be possible—without the discovery of a single new fact—to increase materially the average span of human life and immeasurably to diminish human distress. Sanitarians have often longed for an opportunity to prove the truth of this in a community where the necessary authority and facilities could be provided and thus to show what modern preventive medicine is capable of accomplishing. It seems that in the Island of Guam many of the conditions of such a medical Utopia can be found.

This island, which is solely a naval station, has a native population of 11,636 and a foreign population of 398, about one-half of which is made up of the naval forces. The government is a sort of beneficent autocracy entirely in the hands of naval officers, and all affairs relating to health and sanitation are administered by naval medical officers. There are no other physicians in the colony, and so these officers are charged with the care of the sick. Hospital accommodations are ample and, by means of dressing stations and clinics, relief is extended in all parts of the island. There is provision in segregated colonies for all cases of leprosy and gangosa and a small separate hospital for other communicable diseases. A medical officer detailed as pathologist of the station is engaged in investigating the nature and causes of the diseases peculiar to Guam. Such a rare centralization of medical research, sanitary administration and the care of all classes of the sick makes conditions almost ideal for a practical demonstration in preventive medicine. The fact that more than three-fourths of the native population of the island is concentrated in a large town where overcrowding is extreme and that Guam is afflicted with the usual endemic diseases and with general worm infection simply makes the results of the experiment of so much more interest and value.

In the July issue of the *U. S. Naval Medical Bulletin* one may read what has been accomplished in the short period of American occupation. The reports of the medical officers for 1907 and 1908 are full of interest and should be read in detail by all those interested in tropical sanitation, but the results of the splendid work which has been done are sufficiently well shown by the death rate of 24.3 per 1,000. Some idea of what such a rate means in the tropics may be gained from comparison with the mortality in tropical cities which have long been under the control of European governments, and from the fact that Guam's death rate is exceeded in not a few cities in the United States. Twenty per cent. of the deaths in Guam are caused by guha, an epidemic respiratory disease peculiar to the Ladrone and Caroline Islands. The death rate from all other causes was 19.9. In many countries in Europe such a rate as this would be considered remarkably low at the present time, and there are many communities in the most favored parts of this country which have not yet been able to attain it. The results achieved in the Canal Zone have set a standard for tropical sanitation, but the presence there of a large temporary population within an age period having normally a very low death rate renders comparison with other tropical communities less significant than in the case of Guam.

In Guam it is planned to replace the water supply by means of wells with one from an uncontaminated source and to extend the sewer system. With such means of controlling infection from intestinal parasites it is likely that the vital statistics of this insignificant Pacific isle will assume an importance little dreamed of by those who undertook its sanitation as part of the day's work.

It is a strange commentary on our progress in matters relating to the public health that we must go to the edges of the civilized world for examples of what can be done in the control of disease, but if the true lesson of the splendid victories which have been won in Guam, the Canal Zone and our other tropical possessions is ever fully grasped by those who make and administer the laws in our own country the end of the present sacrifice of human lives from preventable causes will be in sight.

Medical News

CALIFORNIA

Railway Surgeons Meet.—The seventh annual meeting of the Pacific Association of Railway Surgeons was held in San Francisco August 27 and 28, and the following officers were elected: President, Dr. Carl Kurtz, Los Angeles; vice-presidents, Drs. Oliver D. Hamlin, Oakland, and Thomas B. Reardan, Oroville; secretary, Dr. George R. Carson, San Francisco; treasurer, Dr. Ernest M. Keys, Alameda, and member of executive board, Dr. David Powell, Marysville.

Hospitals and Sanatoria.—The Sanatorium of the White Crusaders, Sacramento, for the treatment of patients in the first stages of tuberculosis, was dedicated at Alta August 16. The institution will accommodate thirty patients, and Dr. John

Howard will be resident physician.——Articles of incorporation have been filed by the San Jose General Hospital with capitalization of $25,000.——The Peninsula Hospital, Palo Alto, has leased from Stanford University, the Guild Hospital building for the temporary care of patients, pending the completion of the new Peninsula Hospital.——The hospital at the Odd Fellows' Home, Thermalito, was formally dedicated August 14.——The Fowler Memorial Building at the Pasadena Hospital was dedicated August 25.

COLORADO

Fraternal Sanatorium.—The tuberculosis sanatorium of the Modern Woodmen of America has been formally turned over to the trustees. The site consists of a tract of 1943 acres with a central hospital and a number of cottages.

Personal.—Dr. Thomas D. Palmer, Canon City, has been appointed state penitentiary physician, vice Dr. Frank N. Carrier.——Dr. Charles A. Ellis, Denver, has been appointed official physician to the Trans-Mississippi Congress.——Dr. George H. Stover, Denver, who underwent operation for the removal of thirty cancers on his hand, due it is said, to exposure to the *x*-ray, has recovered and returned to Denver.——Dr. William Booth, Canon City, has been appointed physician of Fremont county.——Dr. Conway B. Ackley was appointed police surgeon of Denver, August 27.

GEORGIA

Fined for Contempt.—In the mayor's court of Athens, August 27, a fine of $100 is said to have been imposed on Dr. W. T. Hamilton for contempt of court, at his failure to appear as a witness after having been summoned.

Osteopathy May Be Legalized.—The House of Representatives, on August 10, passed the Longley Senate Bill, legally recognizing osteopathy in the state, establishing a state board of osteopathic examiners, regulating the practice of osteopathy, and providing that each duly recognized osteopath shall pay a license fee of $10. The bill passed by a vote of 112 to 33. Medical men all over the state have telegraphed and written urging the governor not to approve the bill.

Medical Officers in Camp.—The following medical officers of the Georgia National Guard attended the camp of instruction of medical officers at Antietam, Md.: Major William C. Lyle, Augusta; Major John W. Duncan, Atlanta; Major Clarence H. Willis, Barnesville; Capt. Benjamin E. Pearce, Atlanta; Capt. Martin Cooley, Savannah; Capt. Thomas E. White, Fitzgerald; Capt. Samuel H. Green, Atlanta; Capt. Joseph G. Jarrell, Savannah; Capt. William D. Travis, Covington; First Lieut. Henry P. Adams, Savannah; First Lieut. Henry W. Copeland, Jackson; First Lieut. Robert G. Stephens, and First Lieut. Arnold H. Lindorme, Atlanta.

Free Treatment for Children.—Dr. Stewart R. Roberts, director of medical inspection of the Atlanta public schools, announces that free treatment for diseases of the eye, ear, nose and throat for poor children will be given at Grady Hospital every Friday from two to four by Drs. F. Phinizy Calhoun, Robert B. Ridley, Jr., and Alexander W. Stirling; at the Atlanta College of Physicians and Surgeons on Thursday from 2 to 3:30, by Dr. Abner W. Calhoun, and on Tuesday at 3, by Dr. Dunbar Roy; and at the Atlanta School of Medicine by Dr. J. M. Crawford every Thursday from 1 to 3, and by Dr. Robert B. Ridley, Jr., every Tuesday from 3 to 4.

State Sanatorium Located.—A tract of 257 acres has been purchased for $2,500 near Alto, Habersham county, by the executive committee of the board of trustees for the State Tuberculosis Sanatorium, on which the new sanatorium will be located. The state appropriated $25,000 for the sanatorium, of which $13,000 is available this year. It is proposed to erect an executive building and individual cottages. At the meeting of the trustees in Atlanta August 17, the purchase was confirmed. The members of the executive committee are Capt. W. G. Raoul, Atlanta, T. D. Tinsley, Macon, Dr. Charles H. Richardson, Montezuma, Dr. Marcus F. Carson, Griffin, and Dr. Henry R. Slack, La Grange.

Society Meetings.—The Eighth District Medical Society held its annual meeting in Madison, August 18, and elected the following officers: Dr. Joshua H. Gheesling, Greensboro, president; Dr. Robert W. Trotter, Madison, vice-president; and Dr. Dupree, Athens, secretary-treasurer. The Morgan County Medical Society entertained the society at a barbecue. The next meeting is to be held in Monticello.——At the annual meeting of Troup County Medical Society, held in La Grange, August 26, the following officers were elected: President, Dr. Henry W. Terrell, La Grange; vice-president, Dr. John M. Poer, West Point; secretary-treasurer, Dr. William R. McCall, La Grange; and censors, Drs. Robert H. Jenkins, Hogansville, and Joseph E. Lane

Personal.—Dr. Mark H. Blandford has been elected city physician of Columbus, vice Dr. Charles N. Howard, resigned.——Dr. S. C. Wilson, Augusta, has been elected secretary of the board of health, vice Dr. Edward C. Goodrich, deceased.——Dr. Cyrus W. Strickler has resigned from the board of health of Atlanta.——Dr. James B. Wright, for seven years major and surgeon of the Second Georgia Infantry, has resigned.——Dr. Henry F. Harris, Atlanta, secretary of the State Board of Health, and in charge of the state laboratory, who was operated on for mastoiditis in June, is convalescent.

ILLINOIS

Peoria to Have Tent Colony.—It is planned to have a tent colony in operation in old Prospect Park, Peoria, by the first of next month. The institution is expected to be self-sustaining after the first six months.

Personal.—Dr. Louis J. Linder, East St. Louis, sails for Europe September 11.——Dr. William S. Howell, Winnebago, has been appointed local surgeon for the Northwestern system.——Dr. William C. Day, Whitehall, is reported to be convalescent.——Dr. William G. Caron, Aurora, has been elected supreme treasurer of the Knights of North America.

Hospital Notes.—By the will of the late Judge Solomon H. Bethea, $150,000 is bequeathed to the Dixon Public Hospital, conditionally on the name of the institution being changed to the Katherine Shaw Bethea Hospital.——The new addition to St. Anthony's Hospital, Rockford, was formally dedicated with impressive ceremonies, August 29, by Bishop Muldoon.

Chicago

Personal.—Dr. Frank Billings has returned from Europe.——Dr. William Rittenhouse, who was injured recently in a street car accident, has recovered and resumed practice.

Tuberculosis Camp Closed.—The school for tuberculous children which has been maintained by the board of education and the Chicago Tuberculosis Institute at Seventy-fifth street and Vincennes road for the last five weeks, closed September 2.

Bacteriologist Dismissed.—The civil service commission on September 3 sustained the charges of Health Commissioner Evans against Dr. Joseph F. Biehn and ordered that he "be removed from his office as superintendent of the laboratory of the department of health and from the service of the City of Chicago."

MARYLAND

Pellagra.—Several cases of pellagra have been reported in Charles county, and the secretary of the State Board of Health has gone to investigate the conditions.

Semi-Annual State Meeting.—The semi-annual meeting of the Medical and Chirurgical Faculty of Maryland will be held at Braddock Heights, September 15-17.

Personal.—Dr. Charles A. Wells, Hyattsville, is reported to be seriously ill with disease of the bladder.——Dr. Clarence Nichols, Hudson, left September 3 for a trip of six weeks through Canada and the Pacific Northwest.

Hospital Needed.—The physicians of Queen Anne county are endeavoring to secure a hospital at Centerville. A board of fifteen directors has been appointed. Dr. Laura Ewing Reading, Hayden, has been designated to devise ways and means of carrying out the project.

Baltimore

Anatomists Resign.—Drs. Robert Retzer and Henry McE. McKnower, associates in anatomy in Johns Hopkins Medical School, have resigned to accept similar appointments at the universities of Minnesota and Toronto, respectively.

Hospitals to Have Fire Alarm Boxes.—The fire board has determined to install fire alarm boxes in all hospitals and similar institutions harboring helpless persons. Considerable delay is occasioned in sending in alarms from these institutions by way of the street fire alarm boxes.

Personal.—Dr. Harvey W. Cushing of Johns Hopkins University, gave the William Banks Memorial Lecture at the University of Liverpool, August 4, on "The Pathology and Surgery of Intracranial Tumor."——Dr. Owen Williams, Liverpool, a member of the staff of the Royal Infirmary, has been sent to study methods in use in Johns Hopkins Hospital.——Dr. A. Duval Atkinson has resigned the clinical professorship of medicine in the University of Maryland.——Dr. Walter Van Swearingen Levy has asked the authorities to be allowed to change his surname to Van Swearingen.

MASSACHUSETTS

Personal.—Dr. John A. Barry, Charlestown, was assaulted and severely beaten August 26.——Dr. W. J. Dodd, Boston, has sailed for Europe.

Lodging House Regulations.—The new rules governing lodging houses of Boston apply to the class of houses where the charge for lodging does not exceed twenty-five cents per night. The new rules provide that records shall be kept, that individual towels shall be furnished, and that no spitting on the floors shall be allowed.

To Reduce Infant Mortality.—The sanitary milk committee of Lawrence is cooperating with the physicians of the city in the endeavor to reduce infant mortality, and has undertaken the modifying of milk under the instructions of the attending physicians. Blank formula cards have been issued, to be filled out by the person ordering the milk.

Hospital News.—The state has taken by right of eminent domain all the land lying between Morton, Canterbury, Walkby and Harvard streets, Dorchester. This is the first step in the erection of a great metropolitan district hospital for the insane.——The Babies' Hospital Corporation, Salem, has purchased the old Ropes' Mansion with about nine acres of land, and will use it for a hospital for children.——The Edward Deery home, Ware, has been purchased by the Boston Nurse and Hospital Association, and will be remodeled at once and opened as a hospital.

Ether Day Exercises.—Invitations have been issued by the trustees of the Massachusetts General Hospital to attend the exercises of the sixty-third anniversary of Ether Day, October 16. In the morning demonstrations will be made and operations performed at the hospital, where luncheon will be served at 1 o'clock. The Ether Day exercises proper will take place at 2:30, when diplomas will be presented and an address will be delivered by Charles W. Eliot, LL.D. (M.D., Hon.), and at 7 o'clock the dinner of the Hospital Alumni Association will occur.

MINNESOTA

Personal.—Dr. Hannibal H. Kimball, Minneapolis, sailed for Europe August 18.——Dr. Thomas N. McLean has been appointed local surgeon of the Northern Pacific Railway at Fergus Falls, vice Dr. William T. Duncan, deceased.——Dr. Albert C. Wedge, Albert Lea, has resigned from the state forestry board.

Hospital Notes.—The Von Hagen mansion, Sleepy Eye, has been rented by Dr. G. Schmidt, who will equip the building as a hospital.——The commissioners of St. Louis county have appropriated $20,000 for the construction and maintenance of a tuberculosis sanatorium for the county. The commission appointed to supervise the erection of the sanatorium consists of Mr. George Gray and Dr. Edward L. Tuohy, Duluth, and Mayor Walter J. Smith, Eveleth.

NEW JERSEY

New Quarantine Boat.—The tug boat *Allen*, which has been used for fifteen years for the State Department of Health at Quarantine, has been superseded by the steamer *James Heyer*, a new and modern vessel, and much better adapted to the purpose required.

August Mortality.—There were reported 3,255 deaths in the state, or 46 more than for the corresponding month of 1908. Among the principal causes of death were infantile diarrhea, 656, or 242 more than for the average for the previous twelve months; diseases of the nervous system, 355; tuberculosis, 325; diseases of the circulatory system, 271; diseases of the digestive system, 248; nephritis, 179; cancer, 164; pneumonia, 114; whooping cough, 31; typhoid fever, 29; scarlet fever, 25; diphtheria, 21; and measles, 11.

Destruction of Mosquitoes.—Prof. John B. Smith, head of the New Jersey Entomological Experiment Station, has recently completed a tour of inspection of five counties in the state where the lowlands, soft marshes and meadows have been ditched under his supervision to rid them of the mosquito. Where this work has been done the pest has practically been eliminated. This work was started six years ago in the most populous counties of the state, namely, Essex, Union, Middlesex, Monmouth, and Ocean. Thus far 10,000 acres of meadow and saltwater land have been drained and the cost has been $5 an acre.

Milk Not Cold Enough.—During the first three weeks of August, Charles C. Spear, a milkman of Caldwell, was fined $75 at Montclair, on the charge that the milk he sold was not maintained at the temperature required by the local sanitary code. The defendant intends to appeal the case on the ground that the Montclair Board of Health has no jurisdiction in the matter, as he claims that the milk found to be of a temperature above the 50 degrees required at Montclair, was not for delivery in that place, but in a locality where there is no regulation as to the temperature of the milk to be sold.

Sanatorium Incorporated.—East Lake Sanatorium, Bridgeton, has been incorporated with a capital of $100,000 by Dr. Jacob G. Streets, Joseph Tomlinson and John H. Moore to conduct a hospital and sanitarium.

NEW YORK

Button Day in Albany.—The Woman's Antituberculosis League of Albany attempted on Labor Day to raise money for the cause for which it is working. The city was divided into six districts with twelve substations, and 300 girl button-venders besieged the people of the city to contribute for the cause, and distributed buttons to the donors.

Site for South Shore Hospital.—Property has been purchased near Roosevelt, L. I., for the proposed new hospital of the South Shore Hospital Association, of which Mrs. O. H. P. Belmont is president. Work will be begun as soon as possible and it is hoped that the new hospital will be ready for occupancy by next spring.

New York City

Gives Ambulance.—Former Park Commissioner Elijah Kennedy is so grateful over his recovery from an operation that he is to present to the Long Island College Hospital an ambulance, of which the institution has been in need for a long time.

More Pure Milk Depots.—Two more milk depots, in addition to the seven now in operation, are to be opened. This plan calls for an expenditure of $55,850, part of which sum will be used to carry on an educational campaign among the mothers of the localities in which the milk depots will be established.

Polyclinic Hospital.—The trustees of the New York Polyclinic Hospital have purchased a site for a new hospital between Eighth and Ninth avenues and Fiftieth street. The new hospital will be twelve stories high and will cost about $1,000,000. The old building on Thirty-fourth street will be continued as an east side branch.

Officers of Italian Society.—The officers of the Italian Medical Society, recently organized in New York City, are as follows: President, Dr. Antonio Stella; secretary, Dr. Rocco Bellantoni; treasurer, Dr. Antonio Vernaglia; members of executive committee, Drs. Frank G. Samarelli, Joseph Grana, Louis Criscuoli and Guiseppe Di Santi, and members of the committee on audit, Drs. R. Muoio and Nicola Morano.

School to be Enlarged.—Plans have been filed for enlarging the University Medical School on First avenue, north of Twenty-fifth street. There is to be a six-story building adjoining the Carnegie Laboratory. be furnished with operating wards, sterili ooms, and a series of recovery rooms, in ooms for the university staff and stu will cost about $65,000.

Fresh Air and Work at the Otisville Hospital.—The treatment by exposure of the bodies of children to the rays of the sun, so successful in Seysin, Switzerland, particularly in cases of tuberculosis of the muscles, bones and joints, is to be tried at Otisville. Graduated manual labor for adults will also be tried. The sanitarium is now practically managed by the patients, of whom there are about three hundred. They do all the work except the cooking and the nursing.

Engineers of Health and Hygiene.—Columbia University will give four years to the study of this branch of the engineering department. The first year is identical with that of all the courses in the schools of engineering. In the work of the second year courses in quantitative analysis and microscopy will take the place of two civil engineering courses, and in the third and fourth years the work will be taken up in bacteriology, sanitary biology, physical and biologic analysis of water, municipal sanitation, drainage, heating, ventilation and the principles of sanitary science, public health and hygiene.

Buffalo

Personal.—Dr. E. Lowell Marcy has been appointed assistant surgeon on the staff of the Emergency Hospital.——Dr. G. Brinton Hepp and family have removed to Denver, Colo.——Dr. Julius Ullman has returned from a visit to the Saguenay.

Milk Stations Appointed.—The Fresh Air Commission of Buffalo has appointed several milk stations in settlement houses where modified milk and instructions regarding the care of infants can be obtained.

PENNSYLVANIA

New Site for Tuberculosis Camp.—State Health Commissioner Dixon with Robert S. Conklin, commissioner of forestry, and Dr. Wilbur R. Batt, registrar of vital statistics, visited

Howard will be resident physician.——Articles of incorporation have been filed by the San Jose General Hospital with capitalization of $25,000.——The Peninsula Hospital, Palo Alto, has leased from Stanford University, the Guild Hospital building for the temporary care of patients, pending the completion of the new Peninsula Hospital.——The hospital at the Odd Fellows' Home, Thermalito, was formally dedicated August 14. ——The Fowler Memorial Building at the Pasadena Hospital was dedicated August 25.

COLORADO

Fraternal Sanatorium.—The tuberculosis sanatorium of the Modern Woodmen of America has been formally turned over to the trustees. The site consists of a tract of 1943 acres with a central hospital and a number of cottages.

Personal.—Dr. Thomas D. Palmer, Canon City, has been appointed state penitentiary physician, vice Dr. Frank N. Carrier. ——Dr. Charles A. Ellis, Denver, has been appointed official physician to the Trans-Mississippi Congress.——Dr. George H. Stover, Denver, who underwent operation for the removal of thirty cancers on his hand, due it is said, to exposure to the *x*-ray, has recovered and returned to Denver.——Dr. William Booth, Canon City, has been appointed physician of Fremont county.——Dr. Conway B. Ackley was appointed police surgeon of Denver, August 27.

GEORGIA

Fined for Contempt.—In the mayor's court of Athens, August 27, a fine of $100 is said to have been imposed on Dr. W. T. Hamilton for contempt of court, at his failure to appear as a witness after having been summoned.

Osteopathy May Be Legalized.—The House of Representatives, on August 10, passed the Longley Senate Bill, legally recognizing osteopathy in the state, establishing a state board of osteopathic examiners, regulating the practice of osteopathy, and providing that each duly recognized osteopath shall pay a license fee of $10. The bill passed by a vote of 112 to 33. Medical men all over the state have telegraphed and written urging the governor not to approve the bill.

Medical Officers in Camp.—[illegible] officers of the Georgia National Guard [illegible] instruction of medical officers at Antieta [illegible] C. Lyle, Augusta; Major John W. Duncan, Atlanta; Major Clarence H. Willis, Barnesville; Capt. Benjamin E. Pearce, Atlanta; Capt. Martin Cooley, Savannah; Capt. Thomas E. White, Fitzgerald; Capt. Samuel H. Green, Atlanta; Capt. Joseph G. Jarrell, Savannah; Capt. William D. Travis, Covington; First Lieut. Henry P. Adams, Savannah; First Lieut. Henry W. Copeland, Jackson; First Lieut. Robert G. Stephens, and First Lieut. Arnold H. Lindorme, Atlanta.

Free Treatment for Children.—Dr. Stewart R. Roberts, director of medical inspection of the Atlanta public schools, announces that free treatment for diseases of the eye, ear, nose and throat for poor children will be given at Grady Hospital every Friday from two to four by Drs. F. Phinizy Calhoun, Robert B. Ridley, Jr., and Alexander W. Stirling; at the Atlanta College of Physicians and Surgeons on Thursday from 2 to 3:30, by Dr. Abner W. Calhoun, and on Tuesday at 3, by Dr. Dunbar Roy; and at the Atlanta School of Medicine by Dr. J. M. Crawford every Thursday from 1 to 3, and by Dr. Robert B. Ridley, Jr., every Tuesday from 3 to 4.

State Sanatorium Located.—A tract of 257 acres has been purchased for $2,500 near Alto, Habersham county, by the executive committee of the board of trustees for the State Tuberculosis Sanatorium, on which the new sanatorium will be located. The state appropriated $25,000 for the sanatorium, of which $13,000 is available this year. It is proposed to erect an executive building and individual cottages. At the meeting of the trustees in Atlanta August 17, the purchase was confirmed. The members of the executive committee are Capt. W. G. Raoul, Atlanta, T. D. Tinsley, Macon, Dr. Charles H. Richardson, Montezuma, Dr. Marcus F. Carson, Griffin, and Dr. Henry R. Slack, La Grange.

Society Meetings.—The Eighth District Medical Society held its annual meeting in Madison, August 18, and elected the following officers: Dr. Joshua H. Gheesling, Greensboro, president; Dr. Robert W. Trotter, Madison, vice-president; and Dr. Dupree, Athens, secretary-treasurer. The Morgan County Medical Society entertained the society at a barbecue. The next meeting is to be held in Monticello.——At the annual meeting of Troup County Medical Society, held in La Grange, August 26, the following officers were elected: President, Dr. Henry W. Terrell, La Grange; vice-president, Dr. John M. Poer, West Point; secretary-treasurer, Dr. William R. McCall, La Grange; and censors, Drs. Robert H. Jenkins, Hogansville, and Joseph E. Lane

Personal.—Dr. Mark H. Blandford has been elected city physician of Columbus, vice Dr. Charles N. Howard, resigned. ——Dr. S. C. Wilson, Augusta, has been elected secretary of the board of health, vice Dr. Edward C. Goodrich, deceased. ——Dr. Cyrus W. Strickler has resigned from the board of health of Atlanta.——Dr. James B. Wright, for seven years major and surgeon of the Second Georgia Infantry, has resigned.——Dr. Henry F. Harris, Atlanta, secretary of the State Board of Health, and in charge of the state laboratory, who was operated on for mastoiditis in June, is convalescent.

ILLINOIS

Peoria to Have Tent Colony.—It is planned to have a tent colony in operation in old Prospect Park, Peoria, by the first of next month. The institution is expected to be self-sustaining after the first six months.

Personal.—Dr. Louis J. Linder, East St. Louis, sails for Europe September 11.——Dr. William S. Howell, Winnebago, has been appointed local surgeon for the Northwestern system. ——Dr. William C. Day, Whitehall, is reported to be convalescent.——Dr. William G. Caron, Aurora, has been elected supreme treasurer of the Knights of North America.

Hospital Notes.—By the will of the late Judge Solomon H. Bethea, $150,000 is bequeathed to the Dixon Public Hospital, conditionally on the name of the institution being changed to the Katherine Shaw Bethea Hospital.——The new addition to St. Anthony's Hospital, Rockford, was formally dedicated with impressive ceremonies, August 29, by Bishop Muldoon.

Chicago

Personal.—Dr. Frank Billings has returned from Europe. ——Dr. William Rittenhouse, who was injured recently in a street car accident, has recovered and resumed practice.

Tuberculosis Camp Closed.—The school for tuberculous children which has been maintained by the board of education and the Chicago Tuberculosis Institute at Seventy-fifth street and Vincennes road for the last five weeks, closed September 2.

Bacteriologist Dismissed.—The civil service commission on September 3 sustained the charges of Health Commissioner Evans against Dr. Joseph F. Biehn and ordered that he "be removed from his office as superintendent of the laboratory of the department of health and from the service of the City of Chicago."

MARYLAND

Pellagra.—Several cases of pellagra have been reported in Charles county, and the secretary of the State Board of Health has gone to investigate the conditions.

Semi-Annual State Meeting.—The semi-annual meeting of the Medical and Chirurgical Faculty of Maryland will be held at Braddock Heights, September 15-17.

Personal.—Dr. Charles A. Wells, Hyattsville, is reported to be seriously ill with disease of the bladder.——Dr. Clarence Nichols, Hudson, left September 3 for a trip of six weeks through Canada and the Pacific Northwest.

Hospital Needed.—The physicians of Queen Anne county are endeavoring to secure a hospital at Centerville. A board of fifteen directors has been appointed. Dr. Laura Ewing Reading, Hayden, has been designated to devise ways and means of carrying out the project.

Baltimore

Anatomists Resign.—Drs. Robert Retzer and Henry McE. McKnower, associates in anatomy in Johns Hopkins Medical School, have resigned to accept similar appointments at the universities of Minnesota and Toronto, respectively.

Hospitals to Have Fire Alarm Boxes.—The fire board has determined to install fire alarm boxes in all hospitals and similar institutions harboring helpless persons. Considerable delay is occasioned in sending in alarms from these institutions by way of the street fire alarm boxes.

Personal.—Dr. Harvey W. Cushing of Johns Hopkins University, gave the William Banks Memorial Lecture at the University of Liverpool, August 4, on "The Pathology and Surgery of Intracranial Tumor."——Dr. Owen Williams, Liverpool, a member of the staff of the Royal Infirmary, has been sent to study methods in use in Johns Hopkins Hospital.——Dr. A. Duval Atkinson has resigned the clinical professorship of medicine in the University of Maryland.——Dr. Walter Van Swearingen Levy has asked the authorities to be allowed to change his surname to Van Swearingen.

MASSACHUSETTS

Personal.—Dr. John A. Barry, Charlestown, was assaulted and severely beaten August 26.——Dr. W. J. Dodd, Boston, has sailed for Europe.

Lodging House Regulations.—The new rules governing lodging houses of Boston apply to the class of houses where the charge for lodging does not exceed twenty-five cents per night. The new rules provide that records shall be kept, that individual towels shall be furnished, and that no spitting on the floors shall be allowed.

To Reduce Infant Mortality.—The sanitary milk committee of Lawrence is cooperating with the physicians of the city in the endeavor to reduce infant mortality, and has undertaken the modifying of milk under the instructions of the attending physicians. Blank formula cards have been issued, to be filled out by the person ordering the milk.

Hospital News.—The state has taken by right of eminent domain all the land lying between Morton, Canterbury, Walkby and Harvard streets, Dorchester. This is the first step in the erection of a great metropolitan district hospital for the insane.——The Babies' Hospital Corporation, Salem, has purchased the old Ropes' Mansion with about nine acres of land, and will use it for a hospital for children.——The Edward Deery home, Ware, has been purchased by the Boston Nurse and Hospital Association, and will be remodeled at once and opened as a hospital.

Ether Day Exercises.—Invitations have been issued by the trustees of the Massachusetts General Hospital to attend the exercises of the sixty-third anniversary of Ether Day, October 16. In the morning demonstrations will be made and operations performed at the hospital, where luncheon will be served at 1 o'clock. The Ether Day exercises proper will take place at 2:30, when diplomas will be presented and an address will be delivered by Charles W. Eliot, LL.D. (M.D., Hon.), and at 7 o'clock the dinner of the Hospital Alumni Association will occur.

MINNESOTA

Personal.—Dr. Hannibal H. Kimball, Minneapolis, sailed for Europe August 18.——Dr. Thomas N. McLean has been appointed local surgeon of the Northern Pacific Railway at Fergus Falls, vice Dr. William T. Duncan, deceased.——Dr. Albert C. Wedge, Albert Lea, has resigned from the state forestry board.

Hospital Notes.—The Von Hagen mansion, Sleepy Eye, has been rented by Dr. G. Schmidt, who will equip the building as a hospital.——The commissioners of St. Louis county have appropriated $20,000 for the construction and maintenance of a tuberculosis sanatorium for the county. The commission appointed to supervise the erection of the sanatorium consists of Mr. George Gray and Dr. Edward L. Tuohy, Duluth, and Mayor Walter J. Smith, Eveleth.

NEW JERSEY

New Quarantine Boat.—The tug boat *Allen*, which has been used for fifteen years for the State Department of Health at Quarantine, has been superseded by the steamer *James Heyer*, a new and modern vessel, and much better adapted to the purpose required.

August Mortality.—There were reported 3,255 deaths in the state, or 46 more than for the corresponding month of 1908. Among the principal causes of death were infantile diarrhea, 656, or 242 more than for the average for the previous twelve months; diseases of the nervous system, 355; tuberculosis, 325; diseases of the circulatory system, 271; diseases of the digestive system, 248; nephritis, 179; cancer, 164; pneumonia, 114; whooping cough, 31; typhoid fever, 29; scarlet fever, 25; diphtheria, 21; and measles, 11.

Destruction of Mosquitoes.—Prof. John B. Smith, head of the New Jersey Entomological Experiment Station, has recently completed a tour of inspection of five counties in the state where the lowlands, soft marshes and meadows have been ditched under his supervision to rid them of the mosquito. Where this work has been done the pest has practically been eliminated. This work was started six years ago in the most populous counties of the state, namely, Essex, Union, Middlesex, Monmouth, and Ocean. Thus far 10,000 acres of meadow and saltwater land have been drained and the cost has been $5 an acre.

Milk Not Cold Enough.—During the first three weeks of August, Charles C. Spear, a milkman of Caldwell, was fined $75 at Montclair, on the charge that the milk he sold was not maintained at the temperature required by the local sanitary code. The defendant intends to appeal the case on the ground that the Montclair Board of Health has no jurisdiction in the matter, as he claims that the milk found to be of a temperature above the 50 degrees required at Montclair, was not for delivery in that place, but in a locality where there is no regulation as to the temperature of the milk to be sold.

Sanatorium Incorporated.—East Lake Sanatorium, Bridgeton, has been incorporated with a capital of $100,000 by Dr. Jacob G. Streets, Joseph Tomlinson and John H. Moore to conduct a hospital and sanitarium.

NEW YORK

Button Day in Albany.—The Woman's Antituberculosis League of Albany attempted on Labor Day to raise money for the cause for which it is working. The city was divided into six districts with twelve substations, and 300 girl button-venders besieged the people of the city to contribute for the cause, and distributed buttons to the donors.

Site for South Shore Hospital.—Property has been purchased near Roosevelt, L. I., for the proposed new hospital of the South Shore Hospital Association, of which Mrs. O. H. P. Belmont is president. Work will be begun as soon as possible and it is hoped that the new hospital will be ready for occupancy by next spring.

New York City

Gives Ambulance.—Former Park Commissioner Elijah Kennedy is so grateful over his recovery from an operation that he is to present to the Long Island College Hospital an ambulance, of which the institution has been in need for a long time.

More Pure Milk Depots.—Two more milk depots, in addition to the seven now in operation, are to be opened. This plan calls for an expenditure of $55,850, part of which sum will be used to carry on an educational campaign among the mothers of the localities in which the milk depots will be established.

Polyclinic Hospital.—The trustees of the New York Polyclinic Hospital have purchased a site for a new hospital between Eighth and Ninth avenues and Fiftieth street. The new hospital will be twelve stories high and will cost about $1,000,000. The old building on Thirty-fourth street will be continued as an east side branch.

Officers of Italian Society.—The officers of the Italian Medical Society, recently organized in New York City, are as follows: President, Dr. Antonio Stella; secretary, Dr. Rocco Bellantoni; treasurer, Dr. Antonio Vernaglia; members of executive committee, Drs. Frank G. Samarelli, Joseph Grana, Louis Criscuoli and Guiseppe Di Santi, and members of the committee on audit, Drs. R. Muoio and Nicola Morano.

School to be Enlarged.—Plans have been filed for enlarging the University Medical School on First avenue, north of Twenty-fifth street. There is to be a six-story building adjoining the Carnegie Laboratory. This building is to be furnished with operating wards, sterilizing and etherizing rooms, and a series of recovery rooms, in addition to general rooms for the university staff and students. The building will cost about $65,000.

Fresh Air and Work at the Otisville Hospital.—The treatment by exposure of the bodies of children to the rays of the sun, so successful in Seysin, Switzerland, particularly in cases of tuberculosis of the muscles, bones and joints, is to be tried at Otisville. Graduated manual labor for adults will also be tried. The sanitarium is now practically managed by the patients, of whom there are about three hundred. They do all the work except the cooking and the nursing.

Engineers of Health and Hygiene.—Columbia University will give four years to the study of this branch of the engineering department. The first year is identical with that of all the courses in the schools of engineering. In the work of the second year courses in quantitative analysis and microscopy will take the place of two civil engineering courses, and in the third and fourth years the work will be taken up in bacteriology, sanitary biology, physical and biologic analysis of water, municipal sanitation, drainage, heating, ventilation and the principles of sanitary science, public health and hygiene.

Buffalo

Personal.—Dr. E. Lowell Marcy has been appointed assistant surgeon on the staff of the Emergency Hospital.——Dr. G. Brinton Hepp and family have removed to Denver, Colo.——Dr. Julius Ullman has returned from a visit to the Saguenay.

Milk Stations Appointed.—The Fresh Air Commission of Buffalo has appointed several milk stations in settlement houses where modified milk and instructions regarding the care of infants can be obtained.

PENNSYLVANIA

New Site for Tuberculosis Camp.—State Health Commissioner Dixon with Robert S. Conklin, commissioner of forestry, and Dr. Wilbur R. Batt, registrar of vital statistics, visited the state forestry reservation, Huntingdon county, August 11 and 12, to select a new site for the State Tuberculosis Camp. Dr. Dixon states that a camp for incurables will be established and if the site prove suitable, a camp for incipient cases will also be arranged.

Society Meetings.—The fourth annual meeting of the Fifth Councilor District Medical Society was held in Gettysburg, August 10. The following officers were elected: President, Dr. Walter H. O'Neal, Gettysburg; vice-president, Dr. William E. Wolff, Arendtsville; and secretary-treasurer, Dr. George E. Holtzapple, York. Hanover was selected as the next place of meeting.——Dauphin County Medical Society, at Harrisburg, August 17, recommended the expulsion from the society of all physicians doing lodge or contract practice, and of members meeting and consulting with physicians engaged in lodge or contract practice.——At the sixth annual meeting of the Northwestern Medical Society, composed of members of the medical societies of Warren, Erie, Mercer, Crawford, McKeown and Venango counties, held in Cambridge Springs, August 25, vaccine therapy was the principal subject of discussion. The officers of the previous year were re-elected.

Philadelphia

Milk Dealers Must Be Licensed.—Under the rules drafted by Director Neff of the Bureau of Health, and approved by the state and national authorities, and by the milk exchange, all milk dealers will be required to take out a license issued by the Department of Health. Fresh milk must contain 12 per cent. of milk solids, including 3 per cent. of butter fat; cream must contain 15 per cent. of butter fat, and skim milk 8½ per cent. of milk solids, exclusive of butter fat. Except in the case of modified milk, the addition of ice will be classed as adulteration.

Work Against Tuberculosis.—The Metal Polishers and Buffers International Union has decided to tax its members to found a house for members ill with tuberculosis. The average life of metal polishers is thirty-four years, or six years less than that of ordinary individuals.——The Independent Order of the Sons of Jacob has pledged financial support for the maintenance of a dispensary to be called the Jewish Consumptive Institution, and to work in conjunction with the Philadelphia Jewish Consumptive Sanatorium, Eaglesville. The dispensary is to care for all cases of tuberculosis which cannot be treated in sanatoria.

[illegible]—Dr. John B. Stetson has been provisionally ap[illegible] third assistant bacteriologist of the bureau of health, [illegible]r. Mortimer Herzberg, resigned.——Dr. Joseph P. Walsh [illegible] been appointed consulting physician to the department of tuberculosis in the Philadelphia General Hospital, vice Dr. Lawrence F. Flick, resigned.——Dr. James T. Schell, chief surgeon of the Northwestern General Hospital, had his automobile demolished in a collision with a trolley car, but luckily escaped without injury.——Dr. Allen J. Smith has been appointed dean of the Medical Department of the University of Pennsylvania, vice Dr. Charles H. Frazer, resigned.

VIRGINIA

Physicians Liable to Arrest.—By alleged disregard of the postal regulations prescribing how bacteriologic specimens may be sent through the mails, a number of physicians of the state have been threatened with arrest by the postal authorities.

Building for Physicians.—A building is contemplated in Richmond to be occupied exclusively by physicians and dentists. A lot has been selected in the central part of the city, and the Academy of Medicine has already agreed to rent rooms in the building if erected.

Personal.—Dr. May Farinholt Jones, assistant resident physician at the State Hospital for the Insane, Williamsburg, has resigned.——Dr. Thomas J. Pretlow has been elected health officer of Newport News.——Dr. William D. Tewksbury has been appointed superintendent of the Virginia State Tuberculosis Sanatorium, Katawba.

GENERAL NEWS AND COMMENT

New Hawaiian Hospital.—The Maui, Hawaii, Agricultural Company has erected a hospital at Paia for the accommodation of its employés, at a cost of about $15,000. The hospital is 147x108 feet, two stories in height, and equipped with all modern appliances.

Clinical Research.—A circular letter has been issued signed by Dr. James Krauss, Boston, calling a meeting at John Ware Hall, Boston Medical Library, October 27, at 10 a. m., which has for its objects the establishment of an American Association of Clinical Research; the establishment of clinical research on an incontrovertible scientific basis in hospitals, and the institution of an American Journal of Clinical Research, in which the work of the members of the association and others doing clinical research work in a scientific manner shall be published.

Interstate Club Organized.—The Interstate Medical Club has been organized with a membership composed of physicians living in Breckenridge, Minn., Wahpeton, N. D., and surrounding towns in Minnesota and North Dakota. The following officers have been elected: President, Dr. Timothy O'Brien, Wahpeton, N. D.; vice-president, Dr. Nathan F. Doleman, Tintah, Minn.; secretary, Dr. C. P. Rice, Breckenridge, Minn.; treasurer, Dr. Louis W. Armstrong, Breckenridge, Minn., and censors, Drs. Tobias L. Birberg, Campbell, Minn., A. Victor Young, Hankinson, N. D., and Robert H. Devine, Wahpeton, N. D.

Officers Elected.—At the annual meeting of the Medical Section of the National Fraternal Congress, held in Boston, August 17, the following officers were elected: President, Dr. Wallace K. Harrison, Chicago; vice-presidents, Drs. Isabella M. Holdon, Port Huron, Mich., and Elmore S. Pettyjohn, Topeka, Kan.; secretary, Dr. John G. McConnell, Chicago; and treasurer, Dr. Elizabeth M. Hooper, Port Huron, Mich.——At the International Congress on Psychology, held in Geneva, August 6, the invitation to hold the next congress in Boston in 1913 was accepted. Prof. William James, Cambridge, Mass., was elected honorary president; Prof. James M. Baldwin, Baltimore, president; and Drs. Edward B. Titchener and James McK. Cattell, New York City, vice-presidents.

Congress of Colored Physicians.—At the eleventh annual meeting of the National Medical Association, held in Boston, August 24-26, under the presidency of Dr. Peter A. Johnson, New York City, the oration on medicine was delivered by Dr. Joseph J. France, Portsmouth, Va., on "The Treatment of Lobar Pneumonia." The following officers were elected: President, Dr. Marcus F. Wheatland, Newport, R. I.; vice-president, W. F. Lofton, D.D.S., Washington, D. C.; secretary, Dr. John A. Kenney, Tuskegee, Ala.; treasurer, Dr. A. Wilberforce Williams, Chicago, and executive board, Drs. Nathan F. Mossell, Philadelphia; Robert F. Boyd, Nashville, Tenn.; George C. Hall, Chicago; Albert R. Collins, Washington, D. C.; Mahlon A. Van Horn, Newport, R. I.; Charles H. Shepherd, Durham, N. C.; Amanda V. Gray, Washington, D. C.; G. E. Cannon, Jersey City, N. J., and Willis W. Steers, Decatur, Ala. It was voted to hold the next meeting in Washington, D. C.

Antituberculosis Work Among Negroes.—Surgeon Charles P. Wertenbaker, P. H. and M.-H. Service, has suggested a plan for the organization of an antituberculosis league for negroes. The plan is that the vice-president of each county society call together the leading negro ministers, physicians, teachers, etc., and induce them to start a branch of the league in each negro church in the county. Any colored person may become a member of the branch league by payment of the annual dues, and will receive a certificate of membership and be furnished a button bearing the words, "Colored Antituberculosis League," which surrounds a double red cross. The fund from the annual dues is to be used for the care and treatment of society members of that league as may have tuberculosis, and for dissemination of information by publication and lectures, and the establishment of dispensaries, sanatoria, etc. The state league of Georgia has already completed its organization and a number of branch church leagues have already been formed.

CANADA

Canadian Medical Association.—The forty-second annual meeting of the Canadian Medical Association, held in Winnipeg, Man., August 23 to 25, was in many respects the best meeting in the history of the organization. The attendance was the largest in its history, as 338 registered, and this, in view of the fact that the annual fee had been raised from $2.00 to $5.00, speaks well for the enthusiasm pervading the organization. Perhaps the desire to see established an official medical journal for the association may account for this. The executive council placed this matter in the hands of the finance committee, of which Dr. John T. Fotheringham, Toronto, formerly editor of the *Canada Lancet*, is chairman, with instructions to proceed at once to place the matter before the Canadian medical profession. Dr. William J. Mayo, Rochester, Minn., read a paper on "The Removal of Sigmoid Tumors," and was subsequently made an honorary member of the association. The address in surgery, on "Cancer of the Prostate," was delivered by Dr. James Bell, Montreal; and the address in medicine, on "Certain Aspects of the Typhoid Problem," by Prof. J. George Adami, Montreal. The scientific part of the meeting, which was exceedingly well-arranged, was conducted under five sections: General medicine; surgery; obstetrics and gynecology; pathology; eye, ear, nose and throat. In the latter section, Dr. Richard A. Reeve, Toronto, delivered an address on "The Present Status of [illegible]" and in the section on obstetrics, Dr. Adam [illegible] delivered the address. There was held a [illegible] diseases of the kidney, introduced by Dr. R. P. Campbell, Montreal, who dwelt largely on the technic of cystoscopy. He was followed by Dr. Walter McKeown, Toronto, who attended to the surgical aspect of kidney diseases, particularly confining his attention to movable kidney. Dr. John T. Fotheringham, Toronto, dealt with the subject of treatment. Dr. Mayo also contributed to the discussion on this symposium. One of the features of the meeting was the discussion on interprovincial registration, introduced by Dr. Robert H. W. Powell, Ottawa, who took charge of a resolution in the absence of Dr. Thomas G. Roddick, Montreal, whose name has long been identified with this subject. Dr. Powell, after reviewing this matter thoroughly, fathered a resolution which called for an amendment to the present Canada Medical Act, to the effect that whenever five or more provinces shall cause to be ratified the Canada Medical Act in their respective legislatures, these provinces may have interprovincial registration. Representatives were present from every province and it transpired that each province was in favor of dominion registration, some favoring reciprocity with Great Britain in order to thus bring about interprovincial registration. The executive council appointed a special committee to carry on the work to a successful completion. The general secretary's annual report gave a concise review of the work done by the association during the past eight years, which showed that during that time the membership of the association had grown from 900 to 1,500, which with the new members elected at Winnipeg will bring the total membership up to about 1,700. During the past year the association had been incorporated by act of Parliament. As this has been largely brought about through the efforts of the committee on medical legislation, of which Dr. Adam T. Shillington, Ottawa, is chairman, it was thought best to appoint Dr. Shillington, chairman of the committee on public health and hygiene, so that the matter of a bureau of health for Canada, for which the association has been working the past eight years, might be taken up with renewed vigor. The milk commission, through its chairman, Dr. Charles J. C. O. Hastings, Toronto, gave an extended report of the work it had performed during the past year. Mr. A. McGill, chief analyst for the Dominion, spoke by invitation on the legislation the government is enacting in this connection. Dr. Rutherford, chief veterinarian for the Dominion, spoke at considerable length on tuberculosis. The commission was directed to continue its work and report again at the next meeting. In the opinion of the commission, all milk not officially "certified" should be officially pasteurized. The visiting profession was most hospitably entertained by the profession in Winnipeg. There was a conversazione on the evening of the first day; a smoking concert on the evening of the second day; a garden party on the afternoon of the second day extended by the lieutenant-governor of Manitoba, Sir Daniel MacMillan; an excursion up the Red River, besides numerous private functions. From the public standpoint there was a new feature at this meeting, namely, a public address. This was the first time in the history of the association that this had been attempted, and its success was most pronounced. This popular lecture was delivered by Dr. Hugh A. MacCallum, London, Ont., on "The Mind and Its Method of Action in Causing and Curing Disease." It was decided to meet next year in Toronto. Dr. Adam H. Wright, Toronto, was elected president, and Dr. Richard A. Reeve, Toronto, chairman of the executive council. Dr. George Elliott, Toronto, was re-elected general secretary, and Dr. Henry B. Small, Ottawa, treasurer.

FOREIGN

Pure Food Congress.—The second International Congress for the Repression of Adulteration and Frauds in Foods and Drugs will be held in Paris, October 17-24, under the auspices of the White Cross Society. The general secretary is M. Ch. Franche, 16 Place Vendome, Paris, France, to whom all communications relating to papers should be addressed. The congress is divided into three sections: (1) alimentary technology, (2) hygiene, (3) crude drugs, essential oils and crude aromatic substances, chemical products and mineral waters. Important questions concerning the adulteration and misbranding of food and drugs will be discussed in the congress and action taken thereon. State dairy and food commissioners, food and drug officials of the various states and municipalities and manufacturers of and dealers in foods and drugs are invited to become members and take an active part in the proceedings of the congress by attendance in person, presentation of papers or otherwise. Dr. H. W. Wiley (Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.) has been designated as representative of the White Cross Society in America and will send a pamphlet giving full details and will forward to Paris the names of subscribers and their fees. All who send fees directly to Paris are requested to send Dr. Wiley their names in order that he may have a complete list.

South African Medical Congress.—The eleventh annual South Africa Medical Congress met in Durban, Natal, August 3 to 7. The opening address was delivered by Sir Henry Bale, Chief Justice of the Supreme Court of Natal and Acting Governor of the colony, in which he advocated the establishment of a department of health for united South Africa. The presidential address was delivered by Dr. Dumat. It was devoted chiefly to hygiene and preventive medicine and emphasized the need for study of tropical diseases by army surgeons. Dr. M. MacVicar of Lovedale, Cape Colony, read a paper on "Tuberculosis Among the Colored Population of South Africa." He stated that there are few white communities in the world where tuberculosis is so uncommon as among the Europeans of South Africa, and that this explains the apathy of the colony regarding the tuberculosis problem. Tuberculosis, he said, is now most common among the natives in the places where civilization has been longest established, and it has apparently followed the main line of traffic; just as in tropical Africa it has followed the trade routes from the coast. There are a few places in South Africa in which the disease has hardly yet penetrated. In the Transvaal and Rhodesia it is rare and in Basutaland it is also uncommon. In the Orange River Colony it is rather common; it is still more prevalent in Natal and the eastern parts of Cape Colony, while the center and western parts of Cape Colony are the most tuberculous regions of South Africa, having a mortality from tuberculosis among the natives at least four times that of England and Wales. Dr. MacVicar urged the establishment of government hospitals, sanitaria and day and night camps for tuberculous natives and the enforcement of sanitary regulations for factories. He also urged that instruction in hygiene be given in the schools, colleges and universities. Dr. Ernest Hill, health officer of the Colony of Natal, read a paper on "Death Rates in the Different Sections of the Community of Natal," in which he discussed chiefly the death rate of Hindoo immigrants, who are generally engaged in agricultural industries, mining, miscellaneous subordinate positions, as servants and general laborers. The higher death rate among these people is ascribed to the inferior housing accommodations, poverty, exposure to weather, insanitary surroundings, etc. Tuberculosis among them is three and one-half times as fatal as among Europeans. They are also more susceptible to malaria, diarrheal diseases, syphilis, intestinal parasites, appendicitis, renal diseases, accidents of parturition, general accidents and suicides. Europeans, on the other hand, Dr. Hill states, suffer more from whooping cough, diphtheria, typhoid, cancer, nervous complaints and diseases of the heart and liver. The next congress will meet at Cape Town.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Aug. 28, 1909.

Increase of Insanity

The sixty-third annual report of the Commissioners in Lunacy, which has just been published, shows a continuation of the increase of insanity which has been chronicled in previous years. On January 1 last there were in England and Wales 128,787 persons certified as insane—an increase of 2,703 compared with the previous year. The average annual increase for the last ten years was 2,370. Heredity is considered responsible for 22.6 per cent. of the cases; mental stress for 21.6 per cent. in private cases and 14.6 in pauper; alcohol for 17.3 per cent. in male private cases and 7.1 per cent. in female, and for 24 per cent. in male pauper cases and 9.1 in female. Influenza was responsible for 2.6 per cent. of the cases.

Nursing in Warfare: Enlarged Scope of the Red Cross Society

An important development of the new territorial army scheme "for the organization of voluntary aid in England and Wales" has been made by the War Office. The scheme for consolidating the medical profession into a homogeneous voluntary corps for service at home in time of war has been previously described in THE JOURNAL. A similar plan has now been promulgated for a nursing service. At present there exist in this country two organizations of which the government has made use. These are the Red Cross Society, which was formed to aid the sick and wounded in warfare, and the

the state forestry reservation, Huntingdon county, August 11 and 12, to select a new site for the State Tuberculosis Camp. Dr. Dixon states that a camp for incurables will be established and if the site prove suitable, a camp for incipient cases will also be arranged.

Society Meetings.—The fourth annual meeting of the Fifth Councilor District Medical Society was held in Gettysburg, August 10. The following officers were elected: President, Dr. Walter H. O'Neal, Gettysburg; vice-president, Dr. William E. Wolff, Arendtsville; and secretary-treasurer, Dr. George E. Holtzapple, York. Hanover was selected as the next place of meeting.——Dauphin County Medical Society, at Harrisburg, August 17, recommended the expulsion from the society of all physicians doing lodge or contract practice, and of members meeting and consulting with physicians engaged in lodge or contract practice.——At the sixth annual meeting of the Northwestern Medical Society, composed of members of the medical societies of Warren, Erie, Mercer, Crawford, McKeown and Venango counties, held in Cambridge Springs, August 25, vaccine therapy was the principal subject of discussion. The officers of the previous year were re-elected.

Philadelphia

Milk Dealers Must Be Licensed.—Under the rules drafted by Director Neff of the Bureau of Health, and approved by the state and national authorities, and by the milk exchange, all milk dealers will be required to take out a license issued by the Department of Health. Fresh milk must contain 12 per cent. of milk solids, including 3 per cent. of butter fat; cream must contain 15 per cent. of butter fat, and skim milk 8½ per cent. of milk solids, exclusive of butter fat. Except in the case of modified milk, the addition of ice will be classed as adulteration.

Work Against Tuberculosis.—The Metal Polishers and Buffers International Union has decided to tax its members to found a house for members ill with tuberculosis. The average life of metal polishers is thirty-four years, or six years less than that of ordinary individuals.——The Independent Order of the Sons of Jacob has pledged financial support for the maintenance of a dispensary to be called the Jewish Consumptive Institution, and to work in conjunction with the Philadelphia Jewish Consumptive Sanatorium, Eagleville. The dispensary is to care for all cases of tuberculosis which cannot be treated in sanatoria.

Personal.—Dr. John B. Stetson has been provisionally appointed third assistant bacteriologist of the bureau of health, vice Dr. Mortimer Herzberg, resigned.——Dr. Joseph P. Walsh has been appointed consulting physician to the department of tuberculosis in the Philadelphia General Hospital, vice Dr. Lawrence F. Flick, resigned.——Dr. James T. Schell, chief surgeon of the Northwestern General Hospital, had his automobile demolished in a collision with a trolley car, but luckily escaped without injury.——Dr. Allen J. Smith has been appointed dean of the Medical Department of the University of Pennsylvania, vice Dr. Charles H. Frazer, resigned.

VIRGINIA

Physicians Liable to Arrest.—By alleged disregard of the postal regulations prescribing how bacteriologic specimens may be sent through the mails, a number of physicians of the state have been threatened with arrest by the postal authorities.

Building for Physicians.—A building is contemplated in Richmond to be occupied exclusively by physicians and dentists. A lot has been selected in the central part of the city, and the Academy of Medicine has already agreed to rent rooms in the building if erected.

Personal.—Dr. May Farinholt Jones, assistant resident physician at the State Hospital for the Insane, Williamsburg, has resigned.——Dr. Thomas J. Pretlow has been elected health officer of Newport News.——Dr. William D. Tewksbury has been appointed superintendent of the Virginia State Tuberculosis Sanatorium, Katawba.

GENERAL NEWS AND COMMENT

New Hawaiian Hospital.—The Maui, Hawaii, Agricultural Company has erected a hospital at Paia for the accommodation of its employés, at a cost of about $15,000. The hospital is 147x108 feet, two stories in height, and equipped with all modern appliances.

Clinical Research.—A circular letter has been issued signed by Dr. James Krauss, Boston, calling a meeting at John Ware Hall, Boston Medical Library, October 27, at 10 a. m., which has for its objects the establishment of an American Association of Clinical Research; the establishment of clinical research on an incontrovertible scientific basis in hospitals, and the institution of an American Journal of Clinical Research, in which the work of the members of the association and others doing clinical research work in a scientific manner shall be published.

Interstate Club Organized.—The Interstate Medical Club has been organized with a membership composed of physicians living in Breckenridge, Minn., Wahpeton, N. D., and surrounding towns in Minnesota and North Dakota. The following officers have been elected: President, Dr. Timothy O'Brien, Wahpeton, N. D.; vice-president, Dr. Nathan F. Doleman, Tintah, Minn.; secretary, Dr. C. P. Rice, Breckenridge, Minn.; treasurer, Dr. Louis W. Armstrong, Breckenridge, Minn., and censors, Drs. Tobias L. Birberg, Campbell, Minn., A. Victor Young, Hankinson, N. D., and Robert H. Devine, Wahpeton, N. D.

Officers Elected.—At the annual meeting of the Medical Section of the National Fraternal Congress, held in Boston, August 17, the following officers were elected: President, Dr. Wallace K. Harrison, Chicago; vice-presidents, Drs. Isabella M. Holdon, Port Huron, Mich., and Elmore S. Pettyjohn, Topeka, Kan.; secretary, Dr. John G. McConnell, Chicago; and treasurer, Dr. Elizabeth M. Hooper, Port Huron, Mich.——At the International Congress on Psychology, held in Geneva, August 6, the invitation to hold the next congress in Boston in 1913 was accepted. Prof. William James, Cambridge, Mass., was elected honorary president; Prof. James M. Baldwin, Baltimore, president; and Drs. Edward B. Titchener and James McK. Cattell, New York City, vice-presidents.

Congress of Colored Physicians.—At the eleventh annual meeting of the National Medical Association, held in Boston, August 24-26, under the presidency of Dr. Peter A. Johnson, New York City, the oration on medicine was delivered by Dr. Joseph J. France, Portsmouth, Va., on "The Treatment of Lobar Pneumonia." The following officers were elected: President, Dr. Marcus F. Wheatland, Newport, R. I.; vice-president, W. F. Lofton, D.D.S., Washington, D. C.; secretary, Dr. John A. Kenney, Tuskegee, Ala.; treasurer, Dr. A. Wilberforce Williams, Chicago, and executive board, Drs. Nathan F. Mossell, Philadelphia; Robert F. Boyd, Nashville, Tenn.; George C. Hall, Chicago; Albert R. Collins, Washington, D. C.; Mahlon A. Van Horn, Newport, R. I.; Charles H. Shepherd, Durham, N. C.; Amanda V. Gray, Washington, D. C.; G. E. Cannon, Jersey City, N. J., and Willis W. Steers, Decatur, Ala. It was voted to hold the next meeting in Washington, D. C.

Antituberculosis Work Among Negroes.—Surgeon Charles P. Wertenbaker, P. H. and M.-H. Service, has suggested a plan for the organization of an antituberculosis league for negroes. The plan is that the vice-president of each county society call together the leading negro ministers, physicians, teachers, etc., and induce them to start a branch of the league in each negro church in the county. Any colored person may become a member of the branch league by payment of the annual dues, and will receive a certificate of membership and be furnished a button bearing the words, "Colored Antituberculosis League," which surrounds a double red cross. The fund from the annual dues is to be used for the care and treatment of society members of that league as may have tuberculosis, and for dissemination of information by publication and lectures, and the establishment of dispensaries, sanatoria, etc. The state league of Georgia has already completed its organization and a number of branch church leagues have already been formed.

CANADA

Canadian Medical Association.—The forty-second annual meeting of the Canadian Medical Association, held in Winnipeg, Man., August 23 to 25, was in many respects the best meeting in the history of the organization. The attendance was the largest in its history, as 338 registered, and this, in view of the fact that the annual fee had been raised from $2.00 to $5.00, speaks well for the enthusiasm pervading the organization. Perhaps the desire to see established an official medical journal for the association may account for this. The executive council placed this matter in the hands of the finance committee, of which Dr. John T. Fotheringham, Toronto, formerly editor of the *Canada Lancet*, is chairman, with instructions to proceed at once to place the matter before the Canadian medical profession. Dr. William J. Mayo, Rochester, Minn., read a paper on "The Removal of Sigmoid Tumors," and was subsequently made an honorary member of the association. The address in surgery, on "Cancer of the Prostate," was delivered by Dr. James Bell, Montreal; and the address in medicine, on "Certain Aspects of the Typhoid Problem," by Prof. J. George Adami, Montreal. The scientific part of the meeting, which was exceedingly well-arranged, was conducted under five sections: General medicine; surgery; obstetrics and gynecology; pathology; eye, ear, nose and throat. In the latter section, Dr. Richard A. Reeve, Toronto, delivered an address on "The Present Status of [illegible] the section on obstetrics, Dr. Adam [illegible]red the address. There was held a [illegible] of the kidney, introduced by Dr. R. P. Campbell, Montreal, who dwelt largely on the technic of cystoscopy. He was followed by Dr. Walter McKeown, Toronto, who attended to the surgical aspect of kidney diseases, particularly confining his attention to movable kidney. Dr. John T. Fotheringham, Toronto, dealt with the subject of treatment. Dr. Mayo also contributed to the discussion on this symposium. One of the features of the meeting was the discussion on interprovincial registration, introduced by Dr. Robert H. W. Powell, Ottawa, who took charge of a resolution in the absence of Dr. Thomas G. Roddick, Montreal, whose name has long been identified with this subject. Dr. Powell, after reviewing this matter thoroughly, fathered a resolution which called for an amendment to the present Canada Medical Act, to the effect that whenever five or more provinces shall cause to be ratified the Canada Medical Act in their respective legislatures, these provinces may have interprovincial registration. Representatives were present from every province and it transpired that each province was in favor of dominion registration, some favoring reciprocity with Great Britain in order to thus bring about interprovincial registration. The executive council appointed a special committee to carry on the work to a successful completion. The general secretary's annual report gave a concise review of the work done by the association during the past eight years, which showed that during that time the membership of the association had grown from 900 to 1,500, which with the new members elected at Winnipeg will bring the total membership up to about 1,700. During the past year the association had been incorporated by act of Parliament. As this has been largely brought about through the efforts of the committee on medical legislation, of which Dr. Adam T. Shillington, Ottawa, is chairman, it was thought best to appoint Dr. Shillington, chairman of the committee on public health and hygiene, so that the matter of a bureau of health for Canada, for which the association has been working the past eight years, might be taken up with renewed vigor. The milk commission, through its chairman, Dr. Charles J. C. O. Hastings, Toronto, gave an extended report of the work it had performed during the past year. Mr. A. McGill, chief analyst for the Dominion, spoke by invitation on the legislation the government is enacting in this connection. Dr. Rutherford, chief veterinarian for the Dominion, spoke at considerable length on tuberculosis. The commission was directed to continue its work and report again at the next meeting. In the opinion of the commission, all milk not officially "certified" should be officially pasteurized. The visiting profession was most hospitably entertained by the profession in Winnipeg. There was a conversazione on the evening of the first day; a smoking concert on the evening of the second day; a garden party on the afternoon of the second day extended by the lieutenant-governor of Manitoba, Sir Daniel MacMillan; an excursion up the Red River, besides numerous private functions. From the public standpoint there was a new feature at this meeting, namely, a public address. This was the first time in the history of the association that this had been attempted, and its success was most pronounced. This popular lecture was delivered by Dr. Hugh A. MacCallum, London, Ont., on "The Mind and Its Method of Action in Causing and Curing Disease." It was decided to meet next year in Toronto. Dr. Adam H. Wright, Toronto, was elected president, and Dr. Richard A. Reeve, Toronto, chairman of the executive council. Dr. George Elliott, Toronto, was re-elected general secretary, and Dr. Henry B. Small, Ottawa, treasurer.

FOREIGN

Pure Food Congress.—The second International Congress for the Repression of Adulteration and Frauds in Foods and Drugs will be held in Paris, October 17-24, under the auspices of the White Cross Society. The general secretary is M. Ch. Franche, 16 Place Vendome, Paris, France, to whom all communications relating to papers should be addressed. The congress is divided into three sections: (1) alimentary technology, (2) hygiene, (3) crude drugs, essential oils and crude aromatic substances, chemical products and mineral waters. Important questions concerning the adulteration and misbranding of food and drugs will be discussed in the congress and action taken thereon. State dairy and food commissioners, food and drug officials of the various states and municipalities and manufacturers of and dealers in foods and drugs are invited to become members and take an active part in the proceedings of the congress by attendance in person, presentation of papers or otherwise. Dr. H. W. Wiley (Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.) has been designated as representative of the White Cross Society in America and will send a pamphlet giving full details and will forward to Paris the names of subscribers and their fees. All who send fees directly to Paris are requested to send Dr. Wiley their names in order that he may have a complete list.

South African Medical Congress.—The eleventh annual South Africa Medical Congress met in Durban, Natal, August 3 to 7. The opening address was delivered by Sir Henry Bale, Chief Justice of the Supreme Court of Natal and Acting Governor of the colony, in which he advocated the establishment of a department of health for united South Africa. The presidential address was delivered by Dr. Dumat. It was devoted chiefly to hygiene and preventive medicine and emphasized the need for study of tropical diseases by army surgeons. Dr. M. MacVicar of Lovedale, Cape Colony, read a paper on "Tuberculosis Among the Colored Population of South Africa." He stated that there are few white communities in the world where tuberculosis is so uncommon as among the Europeans of South Africa, and that this explains the apathy of the colony regarding the tuberculosis problem. Tuberculosis, he said, is now most common among the natives in the places where civilization has been longest established, and it has apparently followed the main line of traffic; just as in tropical Africa it has followed the trade routes from the coast. There are a few places in South Africa in which the disease has hardly yet penetrated. In the Transvaal and Rhodesia it is rare and in Basutaland it is also uncommon. In the Orange River Colony it is rather common; it is still more prevalent in Natal and the eastern parts of Cape Colony, while the center and western parts of Cape Colony are the most tuberculous regions of South Africa, having a mortality from tuberculosis among the natives at least four times that of England and Wales. Dr. MacVicar urged the establishment of government hospitals, sanitaria and day and night camps for tuberculous natives and the enforcement of sanitary regulations for factories. He also urged that instruction in hygiene be given in the schools, colleges and universities. Dr. Ernest Hill, health officer of the Colony of Natal, read a paper on "Death Rates in the Different Sections of the Community of Natal," in which he discussed chiefly the death rate of Hindoo immigrants, who are generally engaged in agricultural industries, mining, miscellaneous subordinate positions, as servants and general laborers. The higher death rate among these people is ascribed to the inferior housing accommodations, poverty, exposure to weather, insanitary surroundings, etc. Tuberculosis among them is three and one-half times as fatal as among Europeans. They are also more susceptible to malaria, diarrheal diseases, syphilis, intestinal parasites, appendicitis, renal diseases, accidents of parturition, general accidents and suicides. Europeans, on the other hand, Dr. Hill states, suffer more from whooping cough, diphtheria, typhoid, cancer, nervous complaints and diseases of the heart and liver. The next congress will meet at Cape Town.

LONDON LETTER

(From Our Regular Correspondent)

London, Aug. 28, 1909.

Increase of Insanity

The sixty-third annual report of the Commissioners in Lunacy, which has just been published, shows a continuation of the increase of insanity which has been chronicled in previous years. On January 1 last there were in England and Wales 128,787 persons certified as insane—an increase of 2,703 compared with the previous year. The average annual increase for the last ten years was 2,370. Heredity is considered responsible for 22.6 per cent. of the cases; mental stress for 21.6 per cent. in private cases and 14.6 in pauper; alcohol for 17.3 per cent. in male private cases and 7.1 per cent. in female, and for 24 per cent. in male pauper cases and 9.1 in female. Influenza was responsible for 2.6 per cent. of the cases.

Nursing in Warfare: Enlarged Scope of the Red Cross Society

An important development of the new territorial army scheme "for the organization of voluntary aid in England and Wales" has been made by the War Office. The scheme for consolidating the medical profession into a homogeneous voluntary corps for service at home in time of war has been previously described in The Journal. A similar plan has now been promulgated for a nursing service. At present there exist in this country two organizations of which the government has made use. These are the Red Cross Society, which was formed to aid the sick and wounded in warfare, and the

St. John's Ambulance Association, the object of which is to train persons to render "first aid" in the accidents of civilian life. The new organization is modeled on those which exist in foreign countries, notably Japan and Germany. The county system has been adopted because it is on this that the territorial force is organized. Each county association will, through the medium of the local branches of the Red Cross Society, form "voluntary aid detachments" of men and women. The men's detachments will be specially employed in preparing means of transport by road, in converting local buildings into suitable clearing hospitals for the slightly wounded near the area of operations. They must be thoroughly trained as stretcher-bearers, and to a certain extent as male nurses. Some will be trained in sanitary work such as disinfection of buildings. Each detachment should contain some men who are expert carpenters and mechanics. The women's detachments will be employed chiefly in forming railway rest stations for preparing and serving food to the sick and wounded during evacuation by railway and for taking temporary charge in the evacuation stations or temporary hospitals of the severely wounded who are unable to continue the journey. The Red Cross Society is fully competent to work the new scheme. Its services in time of war have been many and great. To go no farther back than the Franco-Prussian war it then provided $1,100,000 for the aid of the sick and wounded.

The Influence of Feeding on the Development of Jewish and Gentile Children

At the health congress at Leeds, Dr. William Hall read a very interesting paper on a subject of which he had made a special study—"The Influence of Feeding on the Development of Aryan and Semitic Children Born and Bred in Leeds." He pointed out that the Jewish woman possesses the instinct of feeding her child which the Gentile woman has lost. Hence the prevalence of rickets among Gentile children. Fifty years ago bow-legs were uncommon; now they were seen everywhere, but not in the Jews. Ninety per cent. of Jewish mothers fed their children from the breast; from 85 to 90 per cent. of Gentile mothers did not. The poor Jewish woman when pregnant was looked on as a sacred object. She was guarded against alcohol, prolonged labor and insufficient food. The Jewish child had therefore two advantages over the Gentile—before birth and in the first twelve months of life. Later they showed a greater power of resisting infectious diseases; 97 per cent. of them were able to attend school continuously for five years. This power could not be due to their surroundings, for their houses were not clean, and often very dirty. But they had clean food and they freely used oil, fish and eggs. This Dr. Hall regarded as the great secret of their health. During the last six years he had adopted the Jewish method of feeding children and had seen bow-legs straighten out under it

Irish Vital Statistics

The forty-eighth annual report of the Registrar-General for Ireland shows for the first time in more than half a century an increase of population. The increase is small, only 1,853, but its importance is great, as it marks the end of the depletion of the population by emigration. The excess of births over deaths was 25,148, and the loss by emigration 23,295. This is a great decrease on the ordinary emigration figures, which averaged for the decade 1898-1907, 38,036. The most important causes which have led to this decline of emigration are the development of the economic resources of the country, especially agriculture, and the almost complete settlement of the long and bitter agrarian struggle. The marriage rate was 5.2 per 1,000, an increase of 0.1 per cent. compared with the average for the preceding decade.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Aug. 17, 1909.

Personals

I must again begin with the announcement of the death of one of our most distinguished professors. August 16 von Bollinger, professor of pathologic anatomy at Munich, died of heart disease at the age of 66. He was the rector of the University of Munich this year, so that his loss is mourned in wider circles than the medical. He became privat-docent for comparative pathology at Munich in 1870, the next year he accepted a call to Zurich to the newly-established chair of pathologic anatomy and physiology in the veterinary school. At the same time he was privat-docent at the university and a teacher in the agricultural department in the polytechnic school. In 1874 he became professor of pathology in the veterinary school at Munich and of [illegible] the university. In 1880 he was ma[illegible] anatomy and director of the pathologic institute as successor of his former teacher, Professor v. Buhl. His most notable works are the discovery of the actinomycosis fungus, his investigations on the pathology of anthrax, on tuberculosis from food and on the so-called Munich beer-heart. Professor von Bollinger was greatly interested in all that concerns practicing physicians. He took a great part in the development of the *Münchener medizinische Wochenschrift*, being the business manager in the group of fourteen physicians who publish it, and its success is due to him in no small degree.

The Campaign Against Tuberculosis

A police ordinance of the duchy of Anhalt goes to great lengths in limiting the liberty of consumptives in order to prevent the communication of their disease. The ordinance forbids patients of the sanatoria for pulmonary invalids from remaining in the closed rooms of the hotels and saloons. The proprietors are also forbidden to receive temporarily the patients in the enclosed spaces of their premises. The furnishing of alcoholic drinks to the patients is forbidden. The hotel-keepers are also required carefully to clease in hot 2 per cent. soda solution any eating and drinking utensils which have been used by these patients outside of the closed rooms of their places, immediately after their use, and separately from the dishes which are intended for general use.

Centennial of the Berlin University

The centennial jubilee of the Berlin University will be held next year, and the 10th to 12th of October are appointed for the celebration festivities. Oct. 10, 1810, the installation of the first sixteen Berlin professors occurred in the university building; among these the only medical man was the distinguished Hufeland. For the celebration, in addition to a memorial chapel service and a torchlight procession by the students there will be the special assembly, the *Festakt*, in the university hall, at which the present rector of the university, the renowned literary historian, Prof. Erich Schmidt, will deliver an address. The close of the festivities, as is usual in Germany, will be marked by a *Kommers*. In consideration of the great importance of the Berlin University in the development of science in general, and not least of medicine, there is reason to expect that the festival will be largely attended by the people of our own and of foreign countries.

The Imperial Insurance Bill

The strife against the imperial insurance bill has lessened somewhat. A few days ago a convention of the German local *Krankenkassen* was held at which a very decided position was taken in opposition to the demands of physicians. It is officially announced that the bill has been lately discussed by the federal council (*Bundesrat*) and been accepted in its important provisions. But in its details it has received in part some marked alterations. The new bill as it will be presented to the Reichstag for discussion is awaited with anxiety. It will depend essentially on the delegates to the Reichstag to what extent the law will be adapted to the wishes of the medical profession.

Limitation of the Use of Narcotics by Dentists

The employment of narcotics and analgesics by dentists is forbidden by ministerial decree. In pursuance of this the Berlin chief of police has forbidden pharmacists to furnish materials of this kind to dentists.

The German Medical Association at Lübeck

At the annual meeting of the national medical association, the *Aerzte-Vereinsbund*, 333 affiliated associations, with 222,484 members were represented. This is the highest attendance ever recorded.

The most important question taken up at this annual meeting, the *Aerztetag*, held on June 25 and 26, was the proposed imperial insurance law. And, as was to be expected, the association unanimously expressed the opinion that the provisions of the bill which affect the regulation of the relations between physicians and the Kankenkassen would be unacceptable to the medical profession. The association declares that the bill of the imperial insurance law constitutes an exceptional and antagonistic law against physicians and it notifies the imperial government that if this bill shall become a law, no physician belonging to the national medical association, the *Aerzte-Vereinsbund*, will any longer associate himself with industrial insurance. The medical association declares that it will not be satisfied with this legal regulation of the relations between physicians and the insured unless the following demands, not separable from one another, are incorporated in the law: Only those physicians are to be permitted to practice for the Krankenkassen who submit themselves to the conditions of a contract agreed on between the representatives of the organized physicians and the Krankenkassen respectively.

Exceptions shall be permissible only on the basis of general agreements between the Krankenkassen and the representatives of physicians. In every insurance district a commission of contracts must be established on an obligatory footing of equality, to which the agreements between the physicians and the Krankenkassen shall be submitted; also an arbitration committee and arbitration court, on a footing of obligatory equality, for appeal. The right of free medical treatment is, in general, to be limited to those possessing not more than a total income of $480 (2,000 marks).

These propositions and the reasons therefor are to be presented in due form to the federal council; the Reichstag, the governments of the separate states, and the imperial department of the interior. I believe that the government will heed this unanimous declaration of German physicians and that at least the most important of the above mentioned demands will be inserted in the bill. It will have to be subjected to a thorough revision for protests against many of its provisions have been raised by various trade circles. Whether the demands of the physicians will secure a majority in the Reichstag is quite uncertain for the struggle of the physicians, which is surely justified as a fight for their own professional interests but is naturally regarded as in its tendency opposed to the general ideals of social legislation, finds little sympathy among those parties which are interested in social legislation in its widest sense.

Among these parties are included not only the social democrats as representatives of the laboring classes (the majority of the insured) but also a large part of the central and the liberal parties. Should the Reichstag find itself not prepared to comply with the demands of the physicians, we may expect without doubt a severe struggle. If the physicians actually carry out the resolution adopted at the *Aerztetag* to refuse their cooperation in carrying out the social legislation, it might very likely happen that the Reichstag would again introduce the law compelling medical service, according to which every physician is bound to render his assistance in urgent cases. This law existed in Germany until 1869 and naturally was the source of numerous intolerable situations for the medical profession. It will be a severe blow to our liberty if the legislature should resort to such a regulation. Let us hope that this danger will be avoided.

Among the other subjects before the association, the only one of interest to your readers is the report of the hospital commission. The relations of the hospital physicians in many places are still quite faulty, not only with reference to fees but also in the arrangement of the service, inasmuch as many hospital physicians do not have the superintendence, but are to a certain extent the subordinates of "mother superiors," etc. Moreover, in relation to notice of dismissal and to right of pension the hospital physicians have not the standing to which they are entitled. The hospital commission makes the following propositions for the improvement of the position of the physicians: Not merely the medical but the entire superintendence of the hospital with complete independence should be demanded for the physician. He should be appointed by a written contract, should be responsible only to the owner and is to be regarded by the outside world as the official representative of the institution conducted by him. In regard to the management of the institution it may be conducted by the directing physician himself with non-professional boards of managers subordinated to him, or there may be an incorporated managing body (*Kuratorium*, city commission, etc.). In the latter case the following requirements should be enforced: The physician should be chairman or at least should have membership and vote in such a corporation. He should independently decide under all circumstances with reference to the reception, distribution and discharge of patients, the nursing service, the medical part of the correspondence, the hygienic, sanitary and other medical measures in the business conduct of the institution, regarding the supply of medicines, instruments and nursing materials inside the institution. He should be the head of the entire force of employés and have the right to a full insight into the business of the management and cooperation in the choice of employés, the giving of references, the planning of buildings, etc. The directing physician has the right to a sufficient auxiliary service, especially sufficient medical assistance. The subordination of the physician to a layman and the immediate interference of layman and lay commissions, directresses, etc., in the management independently of the physician, should not be permitted. The physician should receive a definite salary, to increase with the period of service, with retiring pension. He should be entitled to demand a fee in the case of all paying patients in the hospital (a discontinuation of the present duty of gratuitous treatment of patients with means). These principles should hold especially for such hospital physicians as occupy the position as their chief employment, and they are to be reasonably adapted to other conditions. Existing relations should be altered only at the desire of the present occupant of the place or on the occurrence of a new appointment.

Pharmacology

Solubility

A knowledge of the solubility of substances is of great importance to the physician, so that he may not order more of an article than will dissolve in the solvent used and so that he may avoid incompatibilities. The Pharmacopeia very properly gives exact information of the solubility of the various drugs.

These facts may be of use to the pharmacist and the chemist, but they are seldom presented in a form to be readily appreciated or easily remembered by the practicing physician. M. I. Wilbert (*Am. Drug. and Pharm. Rec.*, July 12, 1909) suggests that definite values be assigned to certain adjectives by which the limitations of solubility could be expressed without exact figures. He proposes the following definitions for the Pharmacopeia:

Very Soluble: Articles that are soluble in less than 1 part of solvent.
Freely Soluble: From 1 to 10 parts of solvent.
Soluble: From 10 to 100 parts of solvent:
Slightly Soluble: From 100 to 1,000 parts of solvent.
Very Slightly Soluble: From 1,000 to 10,000 parts of solvent.
Nearly Insoluble: From 10,000 to 100,000 parts of solvent.
Practically Insoluble: More than (+) 100,000 parts of solvent.

The same definition might be stated in another form, thus: 100 c.c. of solvent will dissolve 100 gm. or more of a "very soluble" substance; 10 to 100 gm. of a "freely soluble" substance; 1 to 10 gm. of a "soluble" substance; 0.1 to 1 gm. of a "slightly soluble" substance; 0.01 to 0.10 gm. of a "very slightly soluble" substance; 0.001 to 0.01 gm. of a "nearly insoluble" substance; less than 0.001 gm. of a "practically insoluble" substance.

Such terms would be easily understood and if need be could be memorized or the principal official articles could be tabulated as to their solubility for ready reference. The exact solubility of a substance is not readily ascertained since many factors influence this property, notably temperature, physical condition of the substance, and the presence of impurities or of other substances in solution. As a consequence Wilbert shows that there is marked discrepancy between the figures given for the same substance by different authorities. Thus the following is the solubility of acetanilid as given in the several authoritative books:

Solubility in	U.S.P.	B.P.C.	Ph.Brit. Ph.Hisp.	Ph.Ned.	Ph.Helv. Codex.	Ph.Germ. Ph.Belg. Ph.Dan. Ph.Svec.	Ph. Austr.
Water	179	190	200	210	220	230	250
Alcohol ...	2.5	4	3.5	3.6	3.5	3.5	3.5

Attention should be called to the frequent confusion between the terms "slightly" and "difficultly" or "slowly" soluble. A substance difficultly soluble may eventually dissolve in considerable quantity while a substance slightly soluble even if made to enter into solution in quantities above the ordinary limit will separate out on cooling or on standing. Statements of solubility should indicate the temperature and for medical purposes should be calculated for a temperature which is approximately that of the ordinary living room, say 20 C. (68 F.).

Correspondence

Unwise Recommendation of Acetanilid in Heart Failure

To the Editor:—After all the painstaking work done of late to enlighten the profession at large on the dangers of acetanilid et al. (The Journal, July 24, etc.), it is discouraging to me to observe that Dr. A. C. Klebs, in his otherwise valuable work on tuberculosis, just issued, lists acetanilid as a heart-stimulant under the heading, "For Tendency to Heart-Failure," p. 823. While the small dose advised might not prove dangerous, except in advanced cases, it is certainly inconsistent with our knowledge of the physiologic action of acetanilid to recommend it as a remedy to combat heart-failure in a disease in which the heart is most often seriously encumbered.

Erneste Johansen, M.D., San Francisco.

The Smith Operation for Cataract

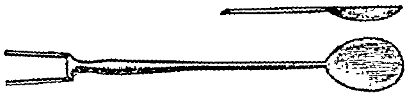
To the Editor:—The paper Dr. Würdemann read at Atlantic City on "Expression of Cataract in Its Capsule" [The Journal, September 4] is misleading to the casual reader.

He quotes as follows from a paper written by Elschnig in 1908: "The lens is expelled after incision of about one-third of the circumference made with a conjunctival flap and an upward iridectomy, either by means of gentle pressure or with the flat spoon acting purely as a gliding surface." Würdemann states that "the above description of Pagenstecher's operation on cataract in the unopened capsule is as short and accurate as has yet been given. Examine these words closely, the various essays of Pagenstecher, digest them, then follow up by reading the essays of subsequent writers, as Cassiani, Gradenigo, Gayet, Landesberg, and other foreign writers, Roosa, Andrew, Henry Smith, Oxley, Maynard, Herbert, Cheney and Greene, then come back to the original of Pagenstecher and give credit for devising the operation in all its details where it belongs, not to later operators, even though of astounding skill, sufficiency and experience."

Again, "But on referring to the original author and in correspondence with German writers, I now fully agree with Elschnig (editor of Czermak's *Augenärztlichen Operationen*) in a letter to me of Feb. 1, 1909, in which he says: 'Pagenstecher's operation is quite the same as Smith's.'"

Dr. Würdemann's paper seems to have been written on the text above quoted from Elschnig's paper of 1908, and all other things made to do service for that quotation. Why does Dr. Würdemann, when enumerating papers by the Pagenstechers, not include any paper written between 1888 and 1908. In 1903 I paid a visit to Pagenstecher and his clinic at Wiesbaden and I have to thank him for his courtesy. He received me in the following terms:

"You are the most interesting man in the world to me. I have advocated extraction in the capsule for the past thirty years, but I have given it up on account of the amount of escape of vitreous. Your operation is quite different. I shall be so much obliged if you will show me how to do it." I then showed him how to do it. Again, "I should be so much obliged if you would preside over me doing it." I did so. He then said: "The best operation in the world, I will now do nothing else."



This explains the hiatus between 1888 and 1908 above noted, and explains why Pagenstecher's operation to-day is the same as Smith's. See the Pagenstecher spoon of the olden days (accompanying illustration). How could this instrument be used as an "inclined plane?" Such is impossible. It was devised to turn concave surface downward after the incision to press on the zonula at the incision and thus dislocate the lens there at least and then to turn concave surface upward to be slipped in through the opening made by thus detaching the zonula, behind the lens and to lift out the lens on it through a "third circumference incision," which means that the capsule would rupture in almost every case. This incision is not big enough, half the circumference would be barely big enough as it has to let out both the spoon and the cataract. Even when no spoon is inserted, the man with considerable experience of the present day operation would be well advised to make his incision half or very nearly half the circumference of the sclero-cornea, if he wishes to avoid mishaps. An incision one-third of the circumference in size, as attributed to Pagenstecher is courting difficulties amounting almost to impossibilities at every step and is courting "slow healing" among other things owing to the excessive manipulation required.

Henry Smith, M.D.
Major Indian Medical Service, Jullendur, India.

The Public Service

Medical Department of the Army

Changes for the week ended Sept. 4, 1909:

Porter, E. H., M. R. C., granted leave of absence for 1 month.

Porter, E. H., M. R. C., relieved from duty at Fort Worden, Wash., to take effect on expiration of leave of absence, and will proceed to his home when he will stand relieved from active duty in the M. R. C.

Hughes, L. S., M. R. C., relieved from duty at Ft. Lawton, Wash., and ordered to Fort Worden, Wash., for duty.

Ford, C. S., major, ordered, on the expiration of his present leave of absence, to proceed to Fort Logan, Colo., for duty.

Coffin, H. L., M. R. C., leave further extended two months.

Le Wald, L. T., capt., leave of absence extended 6 days.

Edger, B. J., Jr., major, granted 2 months' leave of absence, with permission to go beyond the sea, to take effect when discharged from treatment at the Army General Hospital, Presidio of San Francisco.

Wooley, H. C., M. R. C., granted leave of absence for one month, with permission to apply for an extension of one month. So much of par. 18, S. O. 174, July 29, 1909, W. D., as relieves Lt. Wooley from active duty in the M. R. C. is so amended as to take effect on the expiration of his leave of absence.

Kendall, W. P., major, granted leave of absence for one month, to take effect about Sept. 10, 1909.

Hull, A. R., M. R. C., granted thirty days' leave of absence when his services can be spared.

Norman, Seaton, M. R. C., ordered to active duty and assigned to Ft. Leavenworth, Kan.

Philips, H. F., M. R. C., ordered to active duty, and assigned to Ft. Sam Houston, Tex.

McCaw, W. D., Kean, J. R., Lt.-cols., and Ireland, M. W., major, detailed as delegates to represent the medical department of the Army at the meeting of the Association of Military Surgeons of the United States, to be held in Washington, D. C., Oct. 5 to 8, 1909.

Wheate, J. M., M. R. C., ordered from Ft. Lincoln, N. D., to Ft. Snelling, Minn., for temporary duty.

Ware, W. H., dent. surg., ordered to proceed to San Francisco, and on arrival, report by telegraph to the Surgeon General of the Army, for annulment of contract.

Cook, G. W., Jones, E. C., Knox, H. A., Mount, J. R., M. R. C., relieved from duty at their present stations and ordered to report on Oct. 1, 1909, to Col. Valery Havard, M. C., president, Army Medical School, at Washington, D. C., for a course of instruction in that school.

Medical Corps of the Navy

Changes for the week ending Sept. 4, 1909.

Wilson, H. D., surgeon, detached from the *Indiana* and granted leave for two months.

Public Health and Marine-Hospital Service

List of changes for the seven days ended Sept. 1, 1909:

Cofer, L. E., assistant surgeon-general, directed to proceed to Cape Charles Quarantine Station and Fisherman's Island, Va., on special temporary duty.

Rosenau, M. J., surgeon, granted 4 months' leave of absence from Oct. 1, 1909.

Nydegger, J. A., surgeon, granted 1 month and 7 days' leave of absence from Sept. 10, 1909.

Sprague, E. K., surgeon, granted 1 month's leave of absence from Sept. 8, 1909.

Wickes, H. W., P. A. surgeon, granted 15 days' leave of absence from Sept. 1, 1909.

Cumming, Hugh S., P. A. surgeon, leave granted July 8, 1909, amended to read 1 month from Aug. 9, 1909.

Foster, M. H., P. A. surgeon, relieved from duty at Elis Island, N. Y., and detailed to accompany the Agent of the Immigration Board of the Territory of Hawaii to the Madeira and Azores Islands.

Gwyn, M. K., P. A. surgeon, leave granted Aug. 17, 1909, for 7 days from Aug. 17, 1909, amended to read 5 days.

Wille, C. W., P. A. [illegible] ays' leave from Sept. 12.

Boggess, J. S., P. [illegible] from duty on Revenue Cutter *Tahoma*, and [illegible] Chicago, and report to the Medical Officer in Command for duty and assignment.

Stimson, A. M., P. A. surgeon, granted 7 days' leave of absence from Aug. 23, 1909.

Sweet, E. A., P. A. surgeon, relieved from duty at Boston, Mass., and directed to proceed to Ellis Island, N. Y., and report to the Chief Medical Officer for duty.

Wollenberg, R. A. C., asst.-surgeon, directed to proceed to Rotterdam, Holland, on special temporary duty.

Atilles, Pedro del V., acting asst.-surgeon, leave of absence granted Aug. 4, 1909, amended to read 30 days' leave from Aug. 18, 1909, with pay, and 15 days from Sept. 17, 1909, without pay.

Browne, R. W., acting asst.-surgeon, granted 1 day's leave of absence, Aug. 31, 1909.

Cleaves, F. H., acting asst.-surgeon, granted 21 days' leave of absence from Sept. 13, 1909.

Feblan, J. J., acting asst.-surgeon, granted 10 days'. leave of absence from Aug. 28, 1909.

Horning, H., acting asst.-surgeon, granted 7 days' leave of absence from Aug. 23, 1909, under paragraph 210, Service Regulations.

Jackson, J. M., Jr., acting asst.-surgeon, granted 5 days' leave of absence from Aug. 20, 1909.

McLarty, A. A., acting asst.-surgeon, granted 10 days' leave of absence from Aug. 27, 1909.

Spohn, A. E., acting asst.-surgeon, granted 1 month's leave of absence from Aug. 1, 1909, with pay, and 2 months from Sept. 1, 1909, without pay.

PROMOTION

Assistant Surgeon Francis A. Ashford, commissioned a Passed Assistant Surgeon (recess), to rank as such from Aug. 11, 1909.

BOARD CONVENED

Board of medical officers convened to meet at the Marine Hospital office, Galveston, Tex., Aug. 31, 1909, for the purpose of making a physical examination of an officer of the Revenue Cutter Service.. Detail for the board: Passed Assistant Surgeon G. M. Corput, chairman; Acting Assistant Surgeon Wm. H. Gammon, recorder.

Health Reports

The following cases of and deaths from smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended Sept. 3, 1909:

SMALLPOX—UNITED STATES

Illinois: Chicago, Aug. 14-21, 1 case.
Minnesota: Duluth, Aug. 13-20, 1 case.
Montana: General, July1-31, 44 cases.
Ohio: Toledo, July 24-Aug. 7, 2 cases.
Oklahoma: Oklahoma City, Aug. 7-21, 1 case, 1 death.
Tennessee: Knoxville: Aug.14-21, 1 case.
Texas: Houston, March 20-June 19, 20 cases.

SMALLPOX—FOREIGN

Algeria: Algiers, July1-31, 1 death.
Brazil: Bahia, June 25,-July 16, 7 cases, 3 deaths; Pernambuco, May 15-31, 7 deaths.
Chile: Valparaiso, July 3-31, present.
Egypt: Cairo, July 1-8, 1 case, 1 death.
France: Toulon, July 24-31, 1 death.
India: Bombay, July 13-20, 3 deaths; Calcutta, July 3-10, 2 deaths; Rangoon, July 3-17, 4 deaths.
Indo-China: Saigon, July 3-10, 7 cases, 5 deaths.
Italy: General, Aug.1-8, 1 case; Genoa, July 8-15, 2 cases; Naples, Aug. 1-8, 34 cases, 2 deaths.
Portugal: Lisbon, July 31-Aug. 7, 6 cases.
Russia: Odessa, July 24-31, 1 case, 1 death; Riga, July 31-Aug. 7, 4 cases; St. Petersburg, July 17-24, 41 cases, 6 deaths.
Spain: Barcelona, Aug. 3-9, 4 deaths; Madrid, July 1-31, 81 deaths; Valencia, July 24-31, 1 case; Vigo, July 31-Aug. 7, 1 death.
Straits Settlements: Singapore, July 3-10, 1 death.

YELLOW FEVER

Brazil: Bahia, June 25-July 2, 2 cases.
Ecuador: Duran, July 16-31, 3 cases.
Mexico: Colima, July 30-Aug. 26, 8 cases; Merida, Aug. 14, 1 death.

CHOLERA—FOREIGN

China: Amoy, July 17-24, 9 deaths.
India: Bombay, July 13-20, 17 deaths; Calcutta, July 3-10, 28 deaths; Madras, July 10-16, 2 deaths; Rangoon, July 3-17, 9 deaths.
Indo-China: Saigon, June 26-July 3, 3 cases, 3 deaths.
Netherlands: The Rotterdam, Aug. 26, 2 cases.
Russia: St. Petersburg, July 29-Aug. 13, 408 cases, 200 deaths.

PLAGUE

Brazil: Bahia, June 26-July 16, 5 cases, 2 deaths.
China: Amoy, July 17-24, 62 deaths; Canton, June 26-July 17, 45 cases, 34 deaths; Chang-Poo, July 23, epidemic; Kang-be, June 1-30, 61 cases, 59 deaths.
Egypt: General, July 23-29, 7 cases, 2 deaths; Alexandria, July 30-Aug. 2, 3 cases, 2 deaths.
Formosa: General, July 10-17, 3 cases, 3 deaths.
India: General, July 10-17, 800 cases, 613 deaths; Bombay, July 13-20, 25 deaths; Calcutta, July 3-10, 29 deaths; Rangoon, July 3-17, 40 deaths.
Indo-China: Saigon, June 26-July 3, 8 cases, 7 deaths.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

TWO MORE CRITICISMS OF THE LANGUAGE OF MEDICAL WRITERS

To the Editor:—I agree with Dr. Keen's contention in THE JOURNAL (August 14, p. 572) that the use of "data is" is a violation of an obvious rule of grammar; yet I doubt very much whether this practice prevails on a larger scale than that of the unwarranted promiscuous use of "ought" and "should," of which Dr. Keen himself is guilty, when in the closing sentence of his second paragraph he says "But it ought never to occur." "Ought" is a defective verb and denotes a moral or a personal obligation; and "should" is the imperfect from of "shall," and may, though it does not always, imply a social obligation. Thus, we ought to obey the laws; but we should not give offense.. We should be good grammarians; but ought to be honest. Besides, the use of the neuter impersonal pronoun "it," in connection with the verb "ought," is an incongruous combination, and the sentence referred to should, therefore, read, "But it should never occur."

THOMAS J. MAYS, Philadelphia.

To the Editor:—Dr. Keen's letter concerning "data is," reminds me of some other errors in language that are widely prevalent in current medical literature. For instance "appendiceal" appears perhaps oftener than "appendical." While "appendiceal" is more euphonious there is no such word in the dictionaries. The word "starvation" is used incorrectly for "fasting;" and in your last index "fasting" does not appear, but "starvation" is used instead. "Starvation" was first used by Dundas in 1775, and comes from the Anglo-Saxon *steorfan*, "to die." Obviously we can not starve a patient unless we kill him. In a recent and perhaps one of the best works on abdominal surgery, "curetage" appears throughout the book. It should be "curettage." "Sequellæ is a less common mistake for "sequelæ." R. M. HARBIN, Rome, Ga.

ANSWER.—Both our correspondents appear somewhat hypercritical, in that each overlooks the fact that both settled usage and derivation are contributory factors in determining the proper use of words.

Dr. Mays, disregarding derivation, insists on a difference in the kind and degree of obligation expressed respectively by the words "ought" and "should," the former, he feels, implying a primary, intrinsic, or moral obligation, and therefore binding *per se*, while to the latter he accords only a secondary, social or extrinsic obligation. But "shall' (A. S., *sceal*) is the first and third persons singular of the A. S. verb *sculan*, to be obliged, to have to do, to owe (cf. the German *sollen*). At least as late as Chaucer's time "shall" was used as the equivalent of "owe:" "By the faithe I schal to God" (Troylus and Cryseyde, 1. 1600). There is, so far as derivation is concerned, no difference between "you should do it" and "you ought to do it." Both mean, "you owe the doing of it to some authority greater than your own mere volition." The distinction suggested by Dr. Mays, therefore, however convenient, is one to be settled merely by good usage; and it would hardly be difficult to show, from the masters of English literature, that such a distinction is not universal or even general. From this it follows, also, that whatever objection can be directed on the ground of "incongruity" against "it ought" must be equally applicable to "it should."

Dr. Harbin, in his criticism of the common use of "starvation" for mere privation from food, appears to err in the opposite direction. It is not practicable to rely solely on derivation to settle the meaning of words. Would Dr. Harbin, for example, restrict "villain" to its original sense of "a villager" or "knave" to that of "boy"? It is true that originally "to starve" meant to perish; it is allied to the German *sterben*. But in modern usage it means to deprive of nutriment or, in a secondary sense, of some other vital essential, to a degree perilous to life. When we wish to say that some one died from lack of food, it is not enough to say "he starved;" we usually say "he starved to death." We are willing to concede, however, that to describe the therapeutic withholding of food, the word "starvation" is hardly apt; for starvation is, properly speaking, always injurious, though not necessarily fatal; while "fasting" means simply the doing without food, and does not imply any injury. We assume, in any case, that the criticism of the title in our index is directed against the author of the paper, for it is obviously impossible, in indexing, to look up each article in the title of which there might be some slight ambiguity, and ascertain just what the author was talking about.

As to "appendiceal" versus "appendical," we note that while the Standard Dictionary gives "appendical," Dorland has "appendiceal." The English language has not been particularly careful, when adopting adjectival suffixes, etc., to restrict their use to their proper limitations. "Appendiceal" was probably formed on the analogy of "laryngeal," "pharyngeal," which in its turn followed "peritoneal;" but the *e* is in the stem in the last-named word, whereas in laryn-, pharyng-, it is not. These words would have been more correctly formed as laryngal, etc. "Appendiceal" is perhaps more euphonious, and will doubtless hold its own with "laryngeal," rather than be replaced by "appendical" on the more correct analogy of "cervical," "vesical," etc.

As to "curettage"—ignoring the derivation from the French *curette*—we may say that when a word ending with a stressed consonantal syllable adds further syllables, the consonant is generally doubled to retain the stress; cf. defer, deferring, remit, remittance. "Sequellæ" is the result of ignorance, pure and simple, and is one of the words that are constantly misspelled because they are constantly mispronounced. It is not "se-quell-æ," but "se-que-læ." This error is parallel to that of "combatting" for "combating," which has arisen from incorrectly laying the stress on the second, instead of on the first, syllable.

BINDING THE JOURNAL IN FOUR BOOKS A YEAR

To the Editor:—I have had my copies of THE JOURNAL bound for the past six years. The volumes are larger each year, which makes them at the present large, cumbersome and unhandy for ready reference. Can we not just as well have four volumes a year instead of two? E. L. DEWEY, Whiting, Ind.

ANSWER.—There is nothing whatever to prevent anyone who wishes from having his copies of THE JOURNAL bound in four parts to a year, that is, a book for each three months. One of the several sets bound for use in this office is treated in this way. For example, January, February and March of 1909, compose one book labeled "Vol. LII, Part 1," April, May and June are bound in another book labeled "Vol. LII, Part 2." If one wished, one could add the words "With Index" on the back of Part 2, but this is not essential as the user understands that the index is at the end of the second part. As to making four indexes a year, we think that few would prefer this plan. Although it would be an advantage at the immediate time, it would be a disadvantage afterward because it would require twice as much handling to look up an item in back years. A semi-annual index is considered the golden mean. During the issuance of the twenty-six numbers which make up a volume, the majority of readers can find items without much trouble, as they remember the approximate date, and an index is not so necessary. Looking back a year or two years, however, the more indexes there are the more labor there is to find an item, and frequently one wishes that the index were an annual one. Thus the semi-annual index has been evolved as the most desirable arrangement, especially for weekly publications.

One of our readers detaches the pages which are devoted to Current Medical Literature and binds these with the indexes to subjects and to authors. The remainder he binds with the General Index. This plan may commend itself to others.

Association News

NEW MEMBERS

List of new members of the American Medical Association for the month of August, 1909:

ALABAMA

Douglass, A. G., Birmingham.
Heacock, J. D., Birmingham.
McDowell, Wm. P., Eufaula.
Wheeler, W. C., Huntsville.
Williamson, G. W., Montgomery.

CALIFORNIA

Howe, L. P., San Francisco.
Liverman, J. R., San Bernardino.
Taylor, W. S., Livermore.
Taubles, G. H., San Francisco.

COLORADO

Asquith, A. C., Central City.
Burvenich, C. H., Denver.
Fish, J. B., Edgewater.
Ringolsky, Sol, Denver.
Pollock, R. M., Rocky Ford.

CONNECTICUT

Pike, Ernest R., Lakeville.

DISTRICT OF COLUMBIA

Kress, D. H., Takoma Park.
Parker, E. M., Washington.

GEORGIA

Baird, J. B., Jr., Atlanta.
Bradley, Frances, Atlanta.
Redwine, Word, Cassville.
Winchester, W. R., Macon.

ILLINOIS

Gaul, A. C. A., Chicago.
Miller, W. H., Galena.
Morrison, H. T., Jr., Springfield.
Sparling, A. M., Sailor Springs.
Weirick, A. J., Marseilles.

INDIANA

Asbury, W. D., Coalmont.
Hatfield, S. J., Indianapolis.
Randolph, Frank, Elkhart.

IOWA

Bush, F. W., Bagley.
Culverson, F. P., Greenfield.
Distad, O. E., Holmes.
Harper, J. A., Greenfield.
Harris, E. E., Grinnell.
Hearst, G. E., Cedar Falls.
McBurney, G. F., Belmond.
McGregor, J. C., Downey.
Mulhern, T. W., Greenfield.
Mullins, V. S., Atlantic.
Murphy, M. J., Cumberland.
Shelton, C. D., Bloomfield.

KANSAS

Haake, J. A., Peabody.
Yates, Chas. E., Maple Hill.

KENTUCKY

Montfort, Warren, Woodlake.
Perry, J. R., Fords-ferry.
Strother, J. W., Grayson.

LOUISIANA

Breamx, L. J., Scott.

MAINE

McFadyen, James, Hebron.

MARYLAND

Bates, J. H., Forest Park.

MASSACHUSETTS

Gates, R. E., Mansfield.
Hornbrook, F. W., Boston.
Janes, Jr., B. F., Northampton.
Kenealy, J. H., Natick.
Morse, R. S., Worcester.
Murphy, F. P., Lowell.

MICHIGAN

Fuller, R. T., Grand Ledge.
Jones, G. W., Imlay City.
Lee, E. C., Detroit.
Ross, Zimmerman, St. Ignace.

MINNESOTA

Morse, J. H., Minneapolis.

Mills, J. F., Sedro-Woolley.

WEST VIRGINIA

Ridley, F. T., Bluefield.
LeFevre, E. B., Inwood.
Price, R. C., Morgantown.

Marriages

Almerin W. Baer, M.D., Chicago, to Miss Rose Berns of Peabody, Kan., August 28.

Horace Powell Conley, M.D., to Miss Mary Bond Taylor, both of Memphis, Tenn., August 28.

Albert Roy Hogg, M.D., Haralson, Ga., to Miss Gertrude Allen of College Park, Ga., August 24.

Myron E. Bennett, M.D., Chicago, to Mary M. Wheeler, M.D., of Grant Park, Ill., September 6.

John Langdon Chassell, M.D., Belle Fourche, S. D., to Miss Hines, of Rowan, Iowa, September 1.

John Brooks Kaufman, M.D., U. S. Navy, to Miss Katherine Metcalfe, at San Francisco, July 21.

Ernest Collett McKibben, M.D., to Miss Mary Rachel Rogers, both of Vashon, Wash., August 25.

Raymond E. Gaston, M.D., Cincinnati, to Miss Myrtle McCullough, of Tranquility, Ohio, August 18.

William D. Ducy, M.D., Brockton, Mass., to Miss Edna Ramsay of Bath, Maine, at Portland, June 28.

Theodore Alvin Little, M.D., Spartansburg, Pa., to Miss Euphemia Blee of Jerseytown, Pa., August 12.

Leander F. Cain, M.D., Checotah, Okla., to Mrs. Nora M. Fuller of Washington, D. C., at Rockville, Md., August 21.

Deaths

Mason F. Williams, M.D. University of Louisville (Ky.), 1876; a member of the Oklahoma State Medical Association and formerly president of the Muskogee County Medical Society; for more than 30 years a practitioner of the Indian Territory; a member of the local board of U. S. pension examining surgeons; physician to the U. S. jail; physician to Henry Kendall College, and secretary of the first U. S. Medical Examining Board for the Western District of Indian Territory; died in the Muskogee Hospital, August 15, a few hours after operation for peritonitis following rupture of the gall bladder, aged 58.

Charles T. Wilbur, M.D. Berkshire Medical College, Pittsfield, Mass., 1860; a member of the Michigan State Medical Society; assistant surgeon and surgeon of the Fifty-ninth and Ninety-fifth Ohio Volunteer Infantry during the Civil War; from 1876 to 1884 superintendent of the Illinois State Institution for the Feeble-Minded, Lincoln; superintendent and proprietor of the Wilbur Home for the Feeble-Minded, Kalamazoo, Mich.; a member of the board of trustees of the State Institution for the Feeble-Minded, Lapeer; died suddenly at his home in Kalamazoo, August 19, from cerebral embolism, aged 74.

Herman Williams Gross, M.D. University of Pennsylvania, Philadelphia, 1895; a member of the American Medical Association; lieutenant and assistant surgeon of the Sixth Massachusetts Infantry, U. S. V., during the Spanish-American War, with service in Porto Rico; in 1906 a member of the Quincy city council; surgeon to the Fore River Shipbuilding Company, Quincy, Mass.; was found dead in his quarters in the accident hospital of the company, August 24, from the effects of a gunshot wound of the head, believed to have been self-inflicted with suicidal intent, aged 37.

James Stafford, M.D. University of Vermont, Burlington, 1885; College of Physicians and Surgeons, New York City, 1886; formerly attending gynecologist to the Northern Dispensary, New York City; assistant attending gynecologist to the out-patient department of Bellevue Hospital; clinical assistant in gynecology in the New York Policlinic; assistant surgeon of the Seventy-first New York Infantry, U. S. V., and of the Fourth U. S. Infantry in Cuba; died at his home in Perth Amboy, N. J., August 3, from septicemia, aged 48.

Edwin J. Dirickson, M.D. Jefferson Medical College, Philadelphia, 1874; of Berlin, Md.; for many years a member of the Medical and Chirurgical Faculty of Maryland; formerly acting assistant surgeon P. H. and M.-H. Service; physical inspector of the U. S. Life-Saving Service for the fifth district of Maryland; health officer of Ocean City, Md.; and a member of the state legislature; died in the Sheppard and Enoch Pratt Hospital, near Towson, Md., August 27, aged 56.

Homer Bushnell, M.D. University of Michigan, Ann Arbor, 1873; of North Adams, Mass.; a member of the Massachusetts Medical Society and Medical Association of Northern Berkshire; a censor of the Berkshire District Medical Society; and for fifteen years associate medical examiner of the North Berkshire District; died at his summer home near Pownal, Vt., August 23, from cerebral hemorrhage, aged 63.

George Colburn Clement, M.D. Harvard Medical School, Boston, 1880; a member of the American Medical Association; from 1886 to 1892 city physician of Haverhill, Mass.; a member of the board of trustees of and surgeon and opthalmologist to Hale Hospital; local surgeon for the Boston and Northern Street Railway Company; died at his home, August 27, from cerebral hemorrhage, aged 54.

Thomas Simon P. Fitch, M.D. Bellevue Hospital Medical College, New York City, 1867; of Orange, N. J.; a member of the Medical Society of New Jersey; attending physician and member of the visiting staff of Orange Memorial Hospital, and consulting physician to the Orthopedic Hospital and the House of the Good Shepherd, Orange, N. J.; died in Portland, Maine, August 24, aged 64.

Samuel Madison Worthington, M.D. Hahnemann Medical College, Chicago, 1883; of Versailles, Ky.; a member of the Kentucky State Medical Association; a member of the board of directors of the Morgan Helm Memorial Library; died in the Woodford Memorial Hospital, Versailles, August 27, from tuberculosis of the larynx, aged 48.

Alexander M. F. McCollough, M.D. Jefferson Medical College, Philadelphia, 1877; of Los Angeles, Cal.; formerly of Wichita, Kan.; for four years president of the Union Savings Bank, Tacoma, Wash.; died in the Pacific Hospital, Los Angeles, August 19, from peritonitis, after an operation for gallstone disease, aged 56.

Edward Conyers Goodrich, M.D. University of Georgia, Augusta, 1873; a member and in 1900 treasurer of the Medical Association of Georgia; for six years secretary of the health department of Augusta, Ga.; a member of the local board of U. S. pension examining surgeons; died at the home of his brother in Summerville, Ga., August 12, aged 57.

Augustus Franklin Purington, M.D. Medical School of Maine, Brunswick, 1864; of Indiana, Pa.; assistant surgeon in the Army during the Civil War; a member of the Medical Society of the State of Pennsylvania; and formerly president of the Indiana County Medical Society; died at the Markleton Sanitarium, August 19, from heart disease, aged 75.

Levi Coke Stephens, M.D. Medical College of the State of South Carolina, Charleston, 1860; a member and former president of the South Carolina Medical Society and State Board of Medical Examiners; surgeon in the Confederate service during the Civil War; died suddenly at his home in Greenville, August 12, aged 71.

Elmer D. North, M.D. Detroit (Mich.) Medical College, 1881; a veteran of the Civil War; in 1871, superintendent of schools of Ingham county, Mich., and for twenty-one years a member of the local board of U. S. pension examining surgeons; was found dead in his apartment in Lansing, Mich., August 17, from angina pectoris, aged 68.

James M. Borglum, M.D. Homeopathic Medical College of Missouri, St. Louis, 1874; a member of the American Medical Association; for 34 years a practitioner of Omaha; died in his apartments in that city, August 29, from cerebral hemorrhage, five days after a runaway accident, aged 70.

William J. Jones, M.D. New York University, New York City, 1858; a member of the American Medical Association; an honorary fellow and once vice-president of the Medical Society of the State of North Carolina; died at his home in Goldsboro, June 27, aged 71.

Benjamin Ellis Martin, M.D. College of Physicians and Surgeons, New York City, 1861; assistant surgeon of Duryea's Zouaves in the Civil War, and later a member of the Agassiz expedition to South Africa; died at his home in New York City, August 19, aged 70.

Henry Sargent Knight, M.D. Jefferson Medical College, Philadelphia, 1878; a member of the Massachusetts Medical Society; and a member of the school committee of Worcester for many years; died at his home, August 22, from cerebral hemorrhage, aged 50.

Philo William Street, M.D. University of Vermont, Burlington, 1892; formerly a member of the American Medical Association; health officer of Suffield, Conn., and chairman of the school board; died at his home, August 27, from acute nephritis, aged 43.

George Reid (license, Mich., years of practice, 1900); formerly a member of the American Medical Association; for 36 years a practitioner of Reese, Mich.; died recently, at his home in that place from the result of a fall, and was buried August 21.

Zenas Sanford Loftis, M.D. Vanderbilt University, Nashville, 1908; formerly president of the Nashville Student Volunteer Movement; and a missionary at Batang, West China; died from smallpox soon after his arrival at his post of duty, aged 24.

Stella Hager-Colver, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1901; formerly of Philadelphia; a member of the Medical Society of the State of Pennsylvania; died in Dallas, Texas, August 20, from heart disease, after a long illness.

William H. Wells, M.D. Rush Medical College, Chicago, 1848; who went to California in 1849, and afterward practiced in Sacramento, Santa Clara, Solano and Fresno counties; died at the home of his daughter in Sacramento, August 15, aged 91.

William Palmer Wesselhoeft, M.D. Harvard Medical School, Boston, 1857; of Boston; once president of the International Hahnemannian Association; died at his summer home, York Harbor, Maine, August 24, from senile debility, aged 73.

Rhesa W. Read, M.D. University of Pennsylvania, Philadelphia, 1858; major and surgeon in the Confederate service during the Civil War; city physician and health officer of Texarkana, Ark.; died at his home in that city, August 3.

Byron S. Knapp, M.D. Cincinnati College of Medicine and Surgery, 1874; for fifteen years a member of the Owosso (Mich.) Board of Education; died at his home in Owosso, August 20, from cerebral hemorrhage, aged 64.

Jabez Parkhurst Bloss, M.D. College of Physicians and Surgeons, New York City, 1853; for two terms demonstrator of anatomy in the Woodstock (Vt.) Medical College; died at his home in Troy, N. Y., August 26, aged 82.

Frank Eugene Greene, M.D. Eclectic Medical Institute, Cincinnati, 1875; a member and secretary of the New England Society of Specialists; of Roxbury, Boston; died at his summer home in Swampscott, Mass., August 25.

John Emmett Burns, M.D. University of Wooster, Cleveland, 1874; for five years a member of the house staff of Charity Hospital, Cleveland; died at his home in that city, August 18, from heart disease, aged 58.

Robert Walker Robinson, M.D. Long Island College Hospital, Brooklyn, N. Y., 1884; of Auburn, N. Y.; a member of the American Medical Association; died at his summer home in Northport, Maine, August 20, aged 49.

Hamlet Sharp Garland, M.D. Kentucky University, Louisville, 1904; a member of the American Medical Association; died at his home in Oskaloosa, Iowa, August 27, from peritonitis following appendicitis, aged 26.

Samuel M. Plush, M.D. Penn Medical University, Philadelphia, 1876; a veteran of the Civil War, a pioneer in electrical development; died at his home in Arcola, near Pottstown, Pa., May 3, from dropsy, aged 69.

Charles E. L. McCauley, M.D. University of Pennsylvania, Philadelphia, 1853; one of the oldest practitioners of Montgomery county, Tenn.; died at his home in Clarksville, August 14, from senile debility, aged 79.

James William Rochelle, M.D. Kentucky School of Medicine, Louisville, 1893; a member of the State Medical Association of Texas; died at his home in Hooks, August 14, from diabetes and heart disease, aged 56.

Ezekiel Dawson, M.D. University of Pennsylvania, Philadelphia, 1853; surgeon of the Third Delaware Volunteer Infantry during the Civil War; died at his home in Baltimore, June 27, from senile debility, aged 78.

James Milton Carlton, M.D. Medical College of Georgia, Augusta, 1886; a member of the Medical Society of the State of South Carolina; died at his home in Mount Carmel, August 15, from angina pectoris, aged 48.

Allen De Turk Hunter, M.D. Jefferson Medical College, Philadelphia, 1884; a member of the Illinois State Medical Society; died at his home in Savanna, Ill., August 18, after an operation for peritonitis, aged 46.

Louis Feigenblatt, M.D. New York University, New York City, 1872; a member of the Medical Society of the State of New York; died at his home in New York City, May 13, from chronic nephritis, aged 71.

Lewis F. Layton, M.D. Tulane University, New Orleans, 1887; a member of the State Medical Association of Texas; health officer of Cameron county and Brownsville, Texas; died at his home, August 25.

Myron A. Shaw, M.D. Rush Medical College, Chicago, 1883; a veteran of the Civil War; for many years a justice of the peace of Durand, Wis.; died at his home, August 24, from heart disease, aged 72.

William Francis Swalm, M.D. College of Physicians and Surgeons, New York City, 1859; of Brooklyn, N. Y.; a veteran of the Civil War; died at Shelter Island Heights, Long Island, August 26, aged 73.

Henry T. Hunter, M.D. University of Pennsylvania, Philadelphia, 1861; for many years a member of the Medical Society of Virginia; died at his home in Norfolk, Va., August 5, aged 69.

James O. Ackerman, M.D. Hahnemann Medical College, Chicago, 1877; a veteran of the Civil War; died at his home in Fond du Lac, Wis., August 25, from disease of the stomach, aged 67.

James Irving Chapin, M.D. University of Pennsylvania, Philadelphia, 1903; of Philadelphia; died in a hotel in New Orleans, August 24, from the effects of an overdose of morphin, aged 30.

Daniel L. Sweeney, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1882; a member of the Essex County (N. J.) Medical Society; died at his home in Newark, August 20, aged 61.

Louis A. Whitehouse, M.D. Bellevue Hospital Medical College, New York City, 1891; of Brooklyn, N. Y.; died suddenly at the Hotel Garde, New Haven, Conn., August 18, from heart disease.

Charles A. Ball, M.D. George Washington University, Washington, D. C., 1877; a member of the American Medical Association; died at his home in Washington, September 3, aged 58.

Robert Field, M.D. Tulane University, New Orleans, 1868; a Confederate veteran; formerly of Pocahontas, Miss.; died at his home in Hattiesburg, Miss., March 17, from influenza.

J. W. Etheridge, for many years a practitioner of Crystal Springs, Miss.; died at his country home, near that place, January 13, from locomotor ataxia, aged 69.

George A. Martin, M.D. Medical College of Ohio, Cincinnati, 1877; a veteran of the Civil War; died at his home in Brownstown, Ill., August 28, from nephritis, aged 64.

Lewis Harvey Jones, M.D. Barnes Medical College, St. Louis, 1894; died at his home in Ellenboro, W. Va., August 25, from the effects of an accidental overdose of morphin.

John Aloysius Allendorf, M.D. Harvard Medical School, Boston, 1903; of Charlestown, Mass.; died in Carney Hospital, Boston, August 24, from edema of the brain.

Charles Alexander Garnsey (license, Ill., years of practice, 1878); for 65 years a practitioner; died at his home in Batavia, Ill., August 19, aged 95.

John W. Rasmussen, M.D. Marquette University, Milwaukee, Wis., 1898; died at his home in West Allis, Wis., August 27, from acute gastroenteritis, aged 37.

Eleanor Handmacher, M.D. Cleveland Homeopathic Medical College, 1909; of Cleveland; died at St. Alexis' Hospital in that city, August 25, aged 23.

David Sullivan Stevenson, M.D. Lincoln (Neb.) Medical College, 1899; died at his home in Auburn, Neb., July 3, from cancer of the neck, aged 36.

Cyrus Francis Krauser, M.D. Long Island College Hospital, Brooklyn, 1865; formerly of Philadelphia; died in Brooklyn, N. Y., July 9, aged 76.

William S. Cockrell, M.D. University of Maryland, Baltimore, 1879; died at his home near Harper's Ferry, W. Va., August 27, aged 65.

Peter Walter Emmens, M.D. Eclectic Medical Institute, Cincinnati, 1876 of Syracuse, N. Y.; died in Binghamton, N. Y., August 22, aged 78.

C. H. Davidson (license, Utah, years of practice, 1894); died at his home in Brigham, June 12, from carcinoma of the stomach, aged 80.

Roy St. Clair, M.D. Willoughby (Ohio) Medical College, 1858; of Bloomfield, Iowa; died near Humeston, Iowa, July 23, aged 72.

William T. Thurman, M.D. Missouri Medical College, St. Louis, 1885; died at his home in Detroit, Ill., August 25, from nephritis.

John Walker Neil, M.D. Starling Medical College, Columbus, Ohio, 1859; died at his home in Delaware, Ohio, August 4, aged 74.

William Littlewood (license, Mo.); died at his home in Albany, Mo., August 12, from heart disease, aged 64.

Knud L. Boysen, M.D. Kiel, Germany, 1863; died at his home in Chicago, August 25, from nephritis.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARIZONA: Phœnix, October 4-5. Sec., Dr. Ancil Martin.

COLORADO: Capitol, Denver, October 5. Sec., Dr. S. D. VanMeter, 1723 Tremont St.

GEORGIA: Regular, Capitol Bldg., Atlanta, October 12. Sec., Dr. E. R. Anthony, Griffin. Homeopathic: Atlanta, October 4. Sec., Dr. R. E. Hinman, 153 Whitehall St.

IDAHO: Boise, October 5-6. Sec., Dr. W. F. Howard, Pocatello.

ILLINOIS: Coliseum Annex, Chicago, October 20-22. Sec., Dr. J. A. Egan, Springfield.

IOWA: State House, Des Moines, September 21-23. Sec., Dr. Louis A. Thomas.

KANSAS: Topeka, October 12. Sec., Dr. F. P. Hatfield, Olathe.

LOUISIANA: New Orleans, October 1-2. Sec., Dr. Felix A. Larue, 211 Camp St.

MASSACHUSETTS: State House, Boston, September 14-16. Sec., Dr. Edwin B. Harvey.

MICHIGAN: Lansing, October 12-14. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

MINNESOTA: State University, October 5. Sec., Dr. W. S. Fullerton, 214 American National Bank Bldg., St. Paul.

MISSISSIPPI: Jackson, October 12. Sec., Dr. S. H. McLean.

MISSOURI: Kansas City, September 20-22. Sec., Dr. J. A. B. Adcock, Warrensburg.

MONTANA: Capitol, Helena, October 5. Sec., Dr. W. C. Riddell.

NEW JERSEY: State House, Trenton, October 19-20. Sec., Dr. E. L. B. Godfrey, Camden.

NEW YORK: Albany, September 21-24. Chief of Examinations Division, Charles F. Wheelock, Albany.

NORTH DAKOTA: Grand Forks, Oct. 5-7. Sec., Dr. H. M. Wheeler.

OKLAHOMA: Ione Hotel, Guthrie, October 13. Sec., Dr. Frank P. Davis, Enid.

RHODE ISLAND: Room 313, State House, Providence, October 7-8. Sec., Dr. Gardner T. Swarts.

UTAH: Room 207, City and County Bldg., Salt Lake City, October 4-5. Sec., Dr. G. F. Harding, 310 Templeton Bldg.

WYOMING: Laramie, October 20-22. Sec., Dr. S. B. Miller.

Preliminary Education and the College Entrance Examining Board

As has been already stated (THE JOURNAL, Aug. 14, 1909, p. 580), no part of the published standards of colleges and state examining boards has been so badly enforced as that relating to preliminary education, chiefly on account of the endless variety of secondary schools and the extreme difficulty of placing the proper value on entrance credentials. When the student has a diploma from a high school the difficulty is not so great since most universities have lists of "accredited" schools and therefore the standing of the high school can be learned. The difficulty arises when the student presents credentials for a year here, a year there and a year somewhere else, with no diploma from anywhere. This is an instance with no end of variation. The difficult question is: "Has the applicant the equivalent of a four-year high-school education?" State boards are trying to deal with the problem and college deans are struggling with it, but, in spite of all, many deplorably weak and badly prepared students are annually admitted to our medical schools.

What we need to-day more than anything else, is an honest, intelligent enforcement of preliminary requirements. One way to bring this about would be to abolish the "equivalents." When the student has a diploma from a high school which is really accredited by a standard university, admit him. If he doesn't have such a diploma require an examination. Who shall conduct the examination, the college, the state board, a high-school teacher, a state superintendent of public instruction, or some one else? All these plans are in vogue now, resulting in an endless variety and confusion of tests from the signing of certificates in blank or the asking of a few oral questions up to a thorough examination which doubtless really does insure that the applicant has the equivalent of a four-year high-school education.

But why go to all this needless bother and permit this confusion when we have at our very doors a board of entrance examiners, the members of which are chosen because of their skill in deciding the fitness of those who are to enter colleges and universities. A passing mark from the college entrance examining board could be relied on as the best evidence that the student really has the equivalent of the high school education. Why should not all those who do not hold diplomas be referred to this board for examination? That procedure would do away at once with all suspicion of graft, fraud or error and insure that our four-year high-school standard was being strictly adhered to. Any medical school which should insist that all its entrance examinations be conducted by that board would at once place itself above the suspicion of permitting a feeble enforcement of its preliminary standards for the sake of obtaining more students.

That the college entrance examining board furnishes a possible solution to the problem is evidenced by the fact that it already holds entrance examinations for twenty-seven colleges and universities, eight of which have medical departments. Its functions might, with little difficulty, be extended to other colleges and medical schools, since in June, 1908, entrance examinations were held in 165 different cities, in 41 different states, and altogether 3,250 candidates were examined.

But whether that board be chosen to conduct entrance examinations or not, the fact remains that medical education should be lifted above the suspicion of purposely adhering to low standards for the sake of securing fees from a few more students. If any college can not honestly enforce its standards for admission and continue to exist then it should at least die an honorable death.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

The Public Health Movement in Kentucky

The August issue of the *Kentucky Medical Journal* is a Public Health Number and is devoted largely to a discussion of public health matters in Kentucky. It is not only a marked innovation but is also an example to other state society journals of what can be done to awaken interest both in the profession and the public and to inaugurate a sweeping and practical reform along public health lines. The reason for the appearance of the Public Health Number at this time is the work recently completed in Kentucky by Mrs. Caroline B. Crane, who came to Kentucky on the invitation of and under the auspices of the State Federation of Women's Clubs, the public health officers and the medical profession. An introductory editorial says:

"At the request of the State Board of Health, this is made the health number of the *Journal* and is devoted largely to reports made by Mrs. Crane, giving the results of inspections of the various towns and cities visited by her and her final report on 'The Sanitary Condition and Needs of Kentucky.' . . . It is a matter of regret . . . that Mrs. Crane could not be sent to every county in Kentucky. As this could not be done, twelve cities and towns were carefully selected, representing as far as possible every type as to population, water-supply, drainage, dairies, slaughter-houses and other conditions affecting health and life. As some of these conditions she describes and criticizes have their counterpart in every community, rural and urban, health boards, civic leagues and similar organizations can easily utilize them in working out their own problems."

Regarding the results of her work in Kentucky, the *Journal* says:

"Within less than twenty-four hours after her closing meeting in Louisville, the county judge had inspected and condemned the almshouse, and the fiscal court, called in special session for that purpose, had made a generous appropriation for alterations. Prominent laymen called a meeting the following week at Frankfort to organize and inaugurate the reforms suggested by her. There was such a popular demand for dairy reforms and healthy cows that the State Board of Health was enabled to issue a sweeping proclamation providing for the tuberculin test and for improvement in the physical condition of dairies and the handling of milk, and it is hoped that trained settlement workers and nurses will soon be employed in the larger cities and towns to instruct mothers and others in the care and feeding of children and invalids."

The *Journal* also quotes editorially from Mr. Desha Breckenridge, who says in the *Lexington Herald:*

"Irrespective of party every citizen ought to rejoice in any course which will improve the public service and make better conditions in public institutions. Our whole system in Kentucky is rotten. We doubt if there are twenty out of the one hundred and nineteen counties in Kentucky in which the jail is fit for the habitation of hogs much less than human beings. . . . The great majority of our poorhouses are a disgrace to civilization. . . . We are just awakening in Kentucky to the need for the observation of the laws of sanitation, just beginning to understand that there is no higher province of government than care for the health of the citizens. . . . The greatest value from such visits as Mrs. Crane's is the rousing of public conscience, the exciting of the public interest, the increase in the desire of citizens to know conditions in every part of the city in which they live and in every institution supported by the taxes which they pay."

Forty-three pages are devoted to an extended report of the sanitary condition and needs of Kentucky, in which Mrs. Crane summarizes the results of her investigations. The statements made are in each case based on personal observation and knowledge of the facts. In addition, copies of the reports were sent to the State Board of Health, State Pure Food Commission, and the State Federation of Women's Clubs.

A copy of the report on each city was given to the local board of health; and in most instances this report was published in the local papers. After as careful investigation of the sanitary condition and needs of each of the twelve cities as was possible under the circumstances, Mrs. Crane addressed an audience of citizens of the city, setting forth the result of her investigation and making suggestions and recommendations as to the improvement of local conditions. General sanitary conditions in the state were first discussed under the heads of water-supply, sewage and drainage, street sanitation, markets, meat inspection, milk inspection and dairies, school sanitation, tuberculosis, housing conditions, almshouses, jails, workhouses and boards of health, this discussion being followed by special reports on each city visited. Of the twelve cities in question, only five have undertaken any solution of the problem of furnishing pure drinking-water for their citizens. In the other seven, untreated river-water containing the sewage of cities farther up the river is supplied to the citizens by the municipality. These seven cites, although they in the main defend the purity of their water-supply, are seldom free from typhoid fever; yet it is only when there is a violent outbreak and increase in the number of cases that purification of the water-supply is seriously discussed. Mrs. Crane holds that the only solution of the water problem is to furnish pure water, accessible and plentiful to the humblest family, and that a study of vital statistics in the cities which have a pure water-supply should convince any one of the wisdom and economy of this measure. This question is of special interest to women as it affects every household.

Regarding sewerage and drainage, Mrs. Crane states that in almost every one of the cities visited some beautiful creek or river has been transformed into an offensive open sewer by the discharge of the city's sewage into it, making it, especially during the drought of summer, a serious menace to health. Good sewers are worth much more than good roads and each city should, if necessary, issue bonds in order to secure a proper sewage and water-supply system.

Street sanitation and the collection of garbage are very carefully considered in Mrs. Crane's report, and the cremation of all waste is strongly advised. Regarding markets, Mrs. Crane suggests the frequent visitation of committees of good housekeepers into the back rooms and hidden places whence the food supply issues as a remedy for the frightful uncleanliness found in many of these places. Regarding the meat inspection, most of the cities visited seem to be aware of the importance of a clean and wholesome meat supply, but in only a few of them was a sufficient money appropriation made to permit of meat inspection being properly carried on. Special stress is laid on the importance of rigid inspection of dairies, sources of milk-supply and the attention of women's clubs is particularly called to this most important matter. School sanitation, including the consideration of school houses, ventilation, heating and lighting, water-supply and toilet facilities is carefully considered. In this connection Mrs. Crane pertinently remarks:

"Let us remember always that the aim of schools should be to teach children how to live. If we can teach cleanliness and propriety and the use of fresh air, we shall do something worth while. Let us not teach them in the physiology lesson and give the lie to them in the basement."

In discussing housing conditions, Mrs. Crane states that there are in Kentucky, especially in Louisville, Lexington and Frankfort, tenement houses and hovels absolutely unfit for habitation, conditions in Frankfort, the state capital, being by far the worst. Careful consideration is given to county almshouses, in which the inmates were found in many cases to be objects of peculiar neglect, being left almost entirely to their own resources amid surroundings of discomfort, filth and pitiable neglect. Detailed comments of her visits to these reveal almost unbelievable conditions, while the jails are described as medieval types of architecture, unfit places in which to house human beings for any prolonged period. When to the darkness and gloom is added untidiness and filth, these places become hotbeds of disease and contagion as well as schools of crime. Workhouses, local boards of health and state institutions are also carefully considered.

It is impossible to give the details of Mrs. Crane's inspection of the twelve cities visited, but the special reports on these twelve cities should be carefully read by every one interested in public health conditions and problems. These twelve Kentucky cities are probably fair samples of cities of the same size and conditions in other states and, without doubt, an equally careful inspection would reveal as bad or worse conditions in any of our towns and cities. If any county medical society is at a loss to know how to awaken interest in the medical profession of the county and how to secure the cooperation and support of the public, let it take up systematically the inspection of the towns and cities within its boundaries, investigating the sources of water, food and milk-supplies, the manner and effectiveness of sewage and garbage disposal and the condition and management of public institutions, including jails, workhouses, poorhouses, etc. It is safe to say that any county society which will devote two weeks to a careful effort to learn the exact conditons existing along these lines will find that it has discovered all the work which it can possibly do for several years to come, and has brought its energies and activities to bear on questions which are of vital interest to the community.

The best proof of the fact that the times are ripe for such work is the reception given Mrs. Crane by the public press of Kentucky and the large audiences which greeted her everywhere after the nature of her work was understood. Space does not permit of extended quotations, but the following is typical. The Cynthiana *Log Cabin*, commenting on Mrs. Crane's visit, says:

"Cynthiana is having an awakening on the subject of sanitation and it may be that increased diligence on the part of our people may avert an epidemic such as our neighboring city of Georgetown has just experienced. Business was to an extent paralyzed and many lives lost by the recent epidemic of typhoid fever, which was due to contaminated water-supply and filthy premises in some sections of the town. . . . Many people think the Chinese are working backward when they employ doctors by the year to keep them well, but are they? Harrison county and Cynthiana combined spends $300 per year for health officers to avert epidemics while the people themselves pay the doctors $30,000 to $50,000 to treat their diseases. Our people are slowly but surely learning the inestimable value of proper sanitary precautions and cleanliness which will save much sickness in years to come."

The work of Mrs. Crane and of the *Kentucky Medical Journal* has aroused an unprecedented interest in public health matters in Kentucky which will be productive of marked and lasting benefit to all her citizens. The lesson to medical socities is to take up the work that lies nearest at hand and to preach the gospel of modern cleanliness and right living. It has been said that personal cleanliness is a discovery of the last century. Civic cleanliness seems to be a discovery of the last decade. Present conditions offer a wonderful opportunity to the medical profession to lead the way in the campaign for sanitary reform. If we fail to do our duty it will be taken up by others. If we embrace the opportunity the debt of the public to the medical profession, as well as our influence with the people, will be greatly increased.

The question of the proper activities for county and state medical organizations has been much discussed in the past few years which have witnessed such an enormous increase in medical organizations and in the interest displayed in them. In many cases county societies, after preliminary organization work was completed, have apparently been at a loss to know in what direction to turn their energies. A number of county societies, recognizing the constantly growing importance of preventive medicine and the duties of the medical profession to the public in this respect, have taken up some special line of work connected with municipal or county sanitation. This tendency has not been as marked as the importance of the subject demands, but it is an encouraging sign of the possibilities of the future. The work done in Kentucky as set forth in the *Kentucky Journal* may well be taken as a model by our other state associations and state journals. No county can feel that its duty is done so long as sanitary conditions in the county remain uninvestigated and unimproved. In no way will medical societies so clearly demonstrate their reason for existence or so readily secure the support and confidence of the people.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
Bowling Green, Kentucky

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Third Year—First Month, Second Weekly Meeting

Surgery of Chest Wall

Contusions of Thorax: Local symptoms; association of fracture of rib, rupture of lung, pleura or diaphragm. General symptoms; relation of shock to portion of chest injured. Sequelæ, their dependence on viscera injured

Non-Penetrating Injuries of Thorax: Varying character of wounds. Indications in treatment; shock, fractures, hemorrhage, infection.

Penetrating Injuries of Thorax: Character of external wounds. Symptoms; dependence on location and severity of injury; shock, dyspnea, pain, cough. Physical examination, injury to pleura or lung, pleuritic exudate. Prognosis, in fractures, hemorrhage, injury to lung, in gunshot wounds.

Tumors of Chest-Wall: Benign tumors; lipoma, fibroma molluscum, angiomata, keloid, osteoma and chondroma. Malignant tumors; sarcoma and carcinoma, primary or secondary.

Osteomyelitis of Ribs and Sternum: Varieties, septic, typhoid, tuberculous, syphilitic. Differential diagnosis and treatment of tuberculous and syphilitic varieties.

Book Notices

SURGERY OF THE [illegible] In Two Volumes. By John B. Deaver, M.D., LL [illegible] erman Hospital, [illegible], M.D., Surgeon [illegible] Hospital, Phila- [illegible] odenum. Cloth. Pp. 468, with illust [illegible]: P. Blakiston's Son & Co., 1909.

The first 30 pages of this volume are devoted to the topographic anatomy of the stomach and duodenum. The latest views concerning the relations of the viscera in question are given, but we regret that more attention has not been given to a discussion of the duodenojejunal angle. Almost twenty years ago Jonnesco described the anatomy of this angle accurately. Surgeons seem to have overlooked this work almost entirely, and are just beginning to realize that the beginning of the jejunum in about 20 per cent. of the cases passes downward and to the right, while in the remaining 80 per cent. it passes downward and to the left. These two forms are associated with definite fossæ, indicating that the direction of the jejunum in the two cases is anatomic. Jonnesco's work should be reviewed, as it has apparently been forgotten by surgeons. Twenty-five pages are devoted to physiology, in which are embodied the latest views concerning secretin and the interaction of intestinal juices. The chapters devoted to gastric ulcer and carcinoma are worthy of much consideration and will receive general approval.

The statements made concerning the treatment of pyloric stenosis in infants on pages 138, 139 and 140 will be disputed by many. Medical treatment will undoubtedly cure in a spasmodic case, but there is a type which medical treatment will not influence. Delay even of a few days in cases of this type increases the mortality. The large number of deaths in cases of this type is due to the fact that the operation has been performed as a last resort when the patient was in a critical condition. While it may seem "inherently wrong to start children off on what it is hoped may be a long life with their gastrointestinal tract so distorted as it is after even the most skilfully executed gastrojejunostomy," the fact remains that this operation performed in time relieves the condition most rapidly and with the greatest percentage of cures, and in most cases is the only operation that can be attempted with any guarantee of permanent cure with safety.

On page 382 is discussed the position of the primary loop of the jejunum. As previously mentioned Jonnesco described several years ago a number of cases in which this loop of the intestine ran in the inferior layer of the transverse mesocolon, being turned downward and to the right in this way. This relation occurs about as frequently as that described by Mayo, in which there is a mesocolic band. It is still a question whether the division of the band as described by Mayo is not an unessential refinement of technic.

The book is beautifully written and is systematically arranged. The facts concerning the surgery of the stomach and duodenum as they exist at the present time are clearly given. One of the most valuable features of this book is a carefully selected bibliography. It is a volume which both the physician and surgeon should have as a reference book.

SLEEPING SICKNESS BUREAU. Bulletin No. 3. January, 1909. Paper. Pp. 128. London: Sleeping Sickness-Bureau, Royal Society, Burlington House, W., 1909.

This bulletin summarizes the rational prophylaxis against sleeping sickness so far as it is known at this time. A large part of the bulletin is taken up with a consideration of the life history, habits and distribution of the tsetse fly, *Glossina palpalis.* This, of course, is of prime importance, for effective prophylaxis depends to a large degree on a reduction in the number of flies, and on avoidance of localities infected by them. The propagation, the relation of the fly to season, altitude, sun and shade, temperature and humidity, its food supply, enemies and diseases, range of flight, and particularly its close association with bodies of water are discussed.

Methods of prophylaxis are classified under four heads.

1. Attacking the fly in its haunts. The natural abode of the fly is in the brush on the banks of streams or other bodies of water, and here it propagates. It is said that clearing a strip thirty yards wide along the bank of a stream will banish the fly from the strip and also from the country which lies behind it. Pools should be drained or filled, plants noxious to the flies, and animals (birds) which feed on them, should be introduced.

2. The removal of healthy persons from the vicinity of the fly, or their protection from fly-bites. A. Villages or markets should be removed to fly-free areas. B. Occupations carried on in fly areas should be discouraged or forbidden. C. Fly areas should be avoided in the heat of the day, when the flies are most active. D. Roads should be selected which do not traverse fly areas. E. Protection should be afforded by the wearing of suitable clothes, by wire gauze, etc. F. Volatile oily substances should be used to keep off the fly. G. natives should be instructed.

3. The prevention of access of trypanosome-carriers, i. e., infected persons, to fly areas. A. The sick should be segregated away from the fly. B. The moving of persons from infected to uninfected districts, when these contain fly areas, should be prohibited. C. The passage of persons harboring trypanosomes from one infected district to another should be prohibited.

4. Treatment of infected persons, by one of the trypanocidal agents, as sodium aminophenyl arsenate (atoxyl) in order that the peripheral blood may be freed from parasites. In this way the infection of flies may be prevented to some degree.

From this presentation one gains an idea of the herculean task which confronts the colonizers of tropical Africa in their campaign against sleeping sickness.

HANDBOOK OF OBSTETRICS. By R. Cadwallader, A.M., M.D., Assistant in Obstetrics, University of California, Medical Department, San Francisco. Cloth. Pp. 370, with illustrations. Price, $2. Philadelphia: F. A. Davis Co., 1908.

The handbook has advantages over the text-book that probably will be recognized more and more. By the use of thinner paper, slightly smaller type, and thin, somewhat flexible, covers, it is possible to give nearly as much of practical value in 370 pages at the moderate price of $2 as is contained in the ordinary text-book of 600 to 800 pages in a book weighing and costing two or three times as much. Dr. Cadwallader says that he has endeavored to eliminate all possible extraneous matter and to condense into a small volume the essential facts of obstetrics; at the same time he could not resist the temptation to give personal opinions and experiences. In general he has succeeded in his object, but certain blemishes detract from the worth of a book we would otherwise gladly commend.

One of the most obvious defects of the book is the confusion in arrangement of subjects. In the chapter on "Physiologic Puerperium-Fetal" are described asphyxiation of the child, death of the fetus, monstrosities, injuries at birth, umbilical hemorrhage, etc. Inflammation of the decidua is described under "Pathology of Gestation—Fetal." "The Pathology of Pregnancy—Toxemias" is described in Chapter 26, while "Pathology of Gestation—Maternal" is the subject of Chapter 14. The discussion of sepsis is separated by a number of chapters from the pathology of the puerperium.

A number of grammatical errors also show hasty or careless preparation. For example, on page 7 one reads: "Because of the better development of the right side of the body, the right side of the pelvis is often slightly so;" on page 133: "The doctor should call twice daily at first, and as nearly as possible to the minute, for they often worry if he is late." On page 18 "molimina" is misspelled; on page 135 we find the curious plural form "sini," and on page 149 the equally curious "amnia." On page 87 we find the name "Skutsch" misspelled, and on page 108 a mistake in the name "Schultze."

Certain colloquial and facetious phrases are hardly suitable in a scientific book; a few examples of these blemishes may be noted. Reference, in the last paragraph of page 22, to the emotional life of a woman during the obstetrical years, should be omitted; also the advice concerning coitus on page 29: "It should be rare, not as a matter of routine like saying one's prayers or t. i. d." On page 104, speaking of sleep as a dangerous symptom toward the end of labor, Dr. Cadwallader remarks, "I much prefer to hear her swear." Likewise the description of the obstetrical cry on page 104, and the description of the mother's joy on hearing her first-born's cry sound rather out of place. The same can be said of the remark concerning the condition of a patient during the first stage of labor: "'One old hen' remarked to me that at such times she could neither 'lay nor set.'" The remarks on the failure of clergymen to warn their congregations concerning the dangers of criminal abortions would better be omitted, as well as the advice, on page 150, to the physician concerning the management of monstrosities.

Similar evidence of insufficient care in correcting the manuscript or in revising the text appears in some of the scientific statements and rules of treatment. The definition of eutocia on page 99 giving twelve hours as the limit of normal labor and twenty minutes as the length of the third stage is an example; likewise the statement on page 100 that the L. O. A. position occurs in 97 per cent. of all births. On page 112 premature rupture of the membrane is confused with "dry labor." On page 117, discussing the third stage of labor, the singular statement is made that "after half an hour there is danger of the os contracting enough to hold up the placenta like a button in a buttonhole, and it is better to go up and pull down one edge." Speaking of the puerperium, we find: "If it [the baby] cries up will go her temperature and pulse;" on page 144: "Male children should have the foreskin worked back daily and kept from adherence to the glands. . . . In females, the hood of the clitoris should be likewise treated." The following statement, found on page 288, hardly agrees with the average experience: "The use of chloroform (for forceps operation) is not needed except when the woman is very hysterical. It is far better not to use it. There is no pain and this assurance will generally suffice."

It is to be regretted that an author who is evidently a well-informed and interesting teacher should allow inconsiderate statements to disfigure a book that might have been a valuable addition to our obstetric literature.

The Body at Work. By Alex. Hill, M.A., M.D., F.R.C.S., Sometime Master of Downing College, Cambridge. Cloth. Pp. 448, with illustrations. Price, $4.50. New York: Longmans, Green & Co.

This book is not intended for the medical or scientific student but for the amateur. It is therefore written in untechnical language and, although it does not avoid the debatable fields of the subject, it makes no attempt to present the full evidence in any case, and gives only so much of the line of argument as is necessary to an understanding of the conclusion. Mr. Hill forestalls criticism on this score by saying: "If my treatment of vexed questions is unjustifiably dogmatic, this will, I trust, be attributed to the desire to present a definite picture, and not to forgetfulness of considerations which seem to call for qualified statements." He has succeeded in presenting a definite and an interesting picture of the phenomena of life; and, while possessed of considerable mastery over apt phrases and homely, enlightening comparisons, he does not seem to be carried away by his own facility for phrase-making. It is perhaps an excess of scruples against taxing the capacity or patience of the average reader that has led him to omit, "save in a few classical instances," the names of all authorities. While of course elaborate or exhaustive references to authorities would have been out of place in a popular book, we believe that a little more freedom in the citation of the names which are associated with the most important discoveries in physiology would have been of interest as well as of value, even to the unscientific reader.

Manual of Therapeutics. *Referring especially to the Products of the Pharmaceutical and Biological Laboratories of Parke, Davis & Co.* Limp Leather. Pp. 643. For free distribution to physicians, on request. Detroit, 1909.

This is a rather pretentious book for gratuitous distribution. In one way it may be said to be an extended price-list with the prices left off; that is, it is an alphabetical list of the materia medica, itemizing all the forms and combinations in which the various drugs are available. In addition, however, are almost 100 pages of valuable information, such as tables of measures and equivalents, an obstetric calendar, eruptive fever table, food percentages, diet tables, lists of poisons and antidotes, synonyms, a vocabulary of medical Latin, classification of remedies according to physiologic action and classification of remedies by diseases for which they are indicated. These help to make the manual practical and worthy of constant use.

A System of Diet and Dietetics. Edited by G. A. Sutherland, M.D., F.R.C.P. Cloth. Pp. 893. Price, $10.50. New York: Oxford University Press.

The Oxford medical publications have achieved an enviable reputation which this addition to it well sustains. Each of the nineteen contributors to the "system" is responsible for his own department, and, as the editor says, each was asked to give his "own views and experiences rather than to make a collection of all the views of different authorities." Thus the views and methods of practice of these men is given in a way that is very valuable to the practitioner. Unlike many works on dietetics, the book is free from "freak" views and fads, a sane and conservative tone dominating the whole work. This characteristic is nowhere more evident than in the chapter on "Alcohol in Health and Disease," by Dr. Harry Campbell. The least satisfactory chapter in the book is that by J. Rose Bradford, who discusses "Diet in Diabetes" in less than eleven pages. Not only is this subject dealt with in an abbreviated manner which, considering its importance, is entirely unwarranted, but several important points are not touched on at all. For instance, the need of regulating the quantity as well as the kind of food in treating diabetics, is entirely ignored. In an excellent chapter on the treatment of obesity, various fake remedies are shown up and their composition given. Most of these are of British origin and the American physician will be surprised to read in regard to these proprietary fakes that "fortunately thyroid extract is not used, its dangers are too great for even the most reckless advertiser." Evidently Dr. Edmund Cautley, who writes thus, is not familiar with the ways of the American nostrum vendor or he would know that the most widely sold "obesity cures" in this country depend for their action on thyroid extract. The chapters on "The Feeding of Infants and Children in Health" and on "Diet in the Diseases of Children" are by the editor of the "system," Dr. G. A. Sutherland, and both are excellent. The work is one that every physician who realizes the importance of diet in health and disease—and there are few modern physicians who do not—will do well to add to his library. Although this is a large, 900-page book, the light-weight but opaque, unglazed paper makes it easy to handle, while the clear type and widely spaced lines make reading a pleasure.

The Practical Medicine Series. Edited by Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Postgraduate Medical School. Vol. I. General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School. Cloth. Pp. 403, with illustrations. Price, $1.50. Series 1909. Chicago: The Year-Book Publishers.

This is the first of the ten volumes of the series for the present year and is also the first of the two sections that appears on the subject of general medicine. It contains a carefully selected summary of the literature of the preceding year on the diseases of the respiratory and circulatory organs, diseases of the ductless glands, metabolic diseases, and diseases of the kidneys. This volume, in common with the rest of the series, is written primarily for the benefit of the general practitioner and the arrangement and the selection of the subjects adapt it to this purpose. The sections devoted to tuberculosis and diseases of the heart, respectively, deserve especial notice. The book is well illustrated and contains complete indexes, both of subjects and of authors. The volume should prove of more than ordinary interest and value to those physicians who are careful to keep in touch with newer methods of treatment and the more exact methods of diagnosis.

Rudiments of Latin. With Special Reference to the Nomen-
clature of the U. S. Pharmacopeia, ti and
the Text-Books in Materia Medica ar also
Prescription Writing and Notes on th Ger-
man Pharmacopeia. By Julius Willi ofes-
sor of Pharmacy, Purdue University, Pp.
92. Price, $1. Published by the author.

This little book is in no sense an exhaustive one; in fact, Professor Sturmer specifically states that he has included only such portions of grammar as are required for the correct use of medical nomenclature. He has used the same matter in the class-room for several years in manuscript form and has thus tested its efficiency.

Medicolegal

Pyemia, "Pennyroyal Pills" and Evidence in Abortion Case

The Supreme Court of Indiana says, in Carter vs. State, where an indictment charged said Carter with producing a woman named to miscarry from taking "a certain drug, medicine, and substance," that the woman died from "pyemia" (pus in the blood produced by a germ shown to be introduced invariably from the exterior), and that the accused laid stress on the fact of this cause of death, arguing therefrom that some means other than drugs or medicines were used by which infection was produced. But that was simply one presumption built on another. The gravamen (essence) of the offense, under section 2256 of Burns' Annotated Statutes of Indiana of 1908, is prescribing or administering to a pregnant woman, or woman supposed to be pregnant, any drug, medicine, or substance whatever, with intent to produce a miscarriage, or the suggesting, directing, or advising the use of any instrument or means whatever with such intent, whereof the woman miscarries or dies, miscarriage not being necessary to preserve her life. In this case death occurred in about two months after the miscarriage, but the offense is complete when the miscarriage is produced contrary to the statute.

It was insisted by the accused that there was no evidence in the record that the "drug, medicine, or substance" taken by the deceased at his instigation produced the abortion. But the court holds otherwise, it being shown, among other things, that he procured and urged her, over her objection, to take what he told her were pennyroyal pills for the purpose of procuring a miscarriage; that she took them as he directed, taking the last one on Sunday evening, and aborted Thursday night; that she took nothing except what he had given her, and did nothing else. The ingredients of the "pennyroyal pills" which she took were not known or shown, but "pennyroyal pills" are an emmenagogue, and are used for that purpose, and is a name given to some two dozen varieties of compounds of various substances, including ergot, an emmenagogue. It was true that there was evidence that pennyroyal pills will not produce miscarriage, this evidence being based on the supposition that pennyroyal pills are made of pennyroyal; but the evidence also showed that it is a name used for compounds which are emmenagogues, and that they are such compounds, and, while there was no evidence as to the compound in the particular pills, the accused evidently understood their uses, and procured them, and urged the woman to take them for the express purpose of producing her miscarriage.

There was also evidence that no medicine can be said to be sure to produce a miscarriage, and that nothing but mechanical means can be so relied on; but that many kinds of medicine may and do produce miscarriage, depending on the physical condition of the female. The evidence showed that the woman had an adhesive womb, and that the likelihood of miscarriage was greater, both from natural and artificial means, than in case of the normal womb, and it was argued that an abortion was inevitable, and could as well be ascribed to the peculiar condition of the womb as to some unknown drug, medicine, or substance. If the position of the accused was correct on that point, it only accentuated the offense by showing that the woman was in a condition the more readily to abort by the use of pennyroyal pills. But the evidence showed a medicine, drug, or substance given, the specific properties of which were to contract the female womb, and produce menstruation, or miscarriage; that it was procured by the accused, and urged by him to be taken for the specific purpose on his part of producing a miscarriage, and that it was taken as directed by him, and that a miscarriage resulted. The evidence also showed that the woman became very ill, and was unconscious and unattended when the miscarriage resulted, and for a day or two afterward, and the conditions could be better imagined than described, so that the opportunities for the infection from which death actually resulted were doubtless attributable to these conditions, but they did not avoid the force of the evidence on the one question which constituted the crime with which the accused was charged.

Complaint was also made of the refusal of certain evidence offered, claimed as part of the res gestae (essential circumstances of the case)—that some days prior to the taking of medicine the woman had made inquiries as to mechanical methods of producing miscarriage. At most, it could only be an inference that she might have used some mechanical means, and that such means might have produced her miscarriage, and inferences can not be built on inferences. It is manifest that such evidence was not competent as a part of the res gestæ when shown to be a matter of inquiry only, and made some days before the taking of the medicine, and unconnected with any act or declaration of intent, and especially when taken with the other evidence in the case, in which it was disclosed that nothing was used but the drugs procured by the accused, and was clearly not admissible under the evidence and charge here of producing an abortion by medicines or drugs.

Under these circumstances the court holds there was evidence to support every material fact necessary to constitute the offense charged, and affirms a conviction.

Admissible Evidence When Attending Physician Was in Employ of Defendant

The Supreme Court of Minnesota holds, in the personal injury case of Brown vs. Minneapolis, St. Paul & Sault Ste. Marie Railway, Co., that a witness having testified that he knew in whose employ a physician was, it was error to refuse to allow him to state whether or not the physician was in the employ of the defendant. In this case it was sought to fasten on the railway company liability for injuries which it was contended were caused by the explosion of a torpedo negligently left on the track. After the accident the plaintiff was taken to a hospital where his injured eye was removed. It was claimed that a small piece of tin was removed from the eye, and for the purpose of showing that fact, and statements made by the physician, the plaintiff offered to show that the physician was at the time in the employ of the defendant company. As the plantiff's counsel put it, he proposed to show that the physician who performed the operation was the company's physician; in its employ, and that any declaration made by the physician to the plaintiff was admissible in evidence as that of an agent of the company, against interest. The court holds that it was error to exclude the evidence, it being material to the plaintiff's case as it tended to connect the injury with what the plaintiff claimed was the cause of the action. It says that if the physician was, at the time of the operation, in the employ of the railway company, it was competent for the plaintiff to show statements made by him at the time as to the condition of the wound and that the article which he then exhibited to the patient had been taken from the eye.

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

Medical Record, New York

August 28

1 *Serology of Syphilis. R. C. Matson, Portland, Ore.
2 *Scarlatina and Diphtheria Successfully Treated without Medicine. W. H. Thomson, New York.
3 *Large Glioma Growing from the Basal Ganglia Producing Symptoms Suggestive of a Growth in the Frontal Region. T. Diller, Pittsburg.
4 Diagnosis of Tricuspid Stenosis. D. Felberbaum, New York.
5 Unusually Intractable Case of Iritis. Etiology of Iritis. W. C. Posey, Philadelphia.
6 Early Diagnosis of Pulmonary Tuberculosis. L. M. Gaines, Atlanta, Ga.
7 *Estimation of the Urinary Ammonia; and New Instrument for its Rapid Estimation. H. R. Harrower, Chicago.

1. Serology of Syphilis.—Speaking of the Wassermann reaction, Matson says that the rarity of a positive reaction in normal serum and the high percentage of positive reactions in syphilis or suspected cases clearly shows the test to be of much value. A positive reaction is found with the greatest frequency in early cases, and least frequently in latent cases.

A positive reaction means that active syphilis exists, but does not necessarily mean that the present pathologic condition is due to syphilis that must be determined clinically; but it does indicate that there should be a trial of antisyphilitic treatment. A negative result may be interpreted in many different ways. A negative reaction occurring in one who has had syphilis does not mean absolutely that the patient is well, but that the infection, if present at all, is quiescent. If a negative reaction occurs in an early suspected case, it is from 95 to 100 per cent. against syphilis. If obtained in a suspected secondary case, the chances are from 75 to 95 per cent. against syphilis. If obtained in a suspected latent case, the chances are from 50 to 75 per cent. against syphilis. If obtained in a suspected parasyphilitic case, the chances are 70 to 80 per cent. against its existence. Since antisyphilitic treatment may cause the reaction to disappear it may be an index as to the efficiency of a line of treatment in that particular case.

2. Abstracted in The Journal, June 19, 1909, p. 2017.

3. **Glioma of Basal Ganglia.**—Diller describes a case of glioma of the brain with optic neuritis, headache, confusions, slowness of mind, loss of memory and absence of any hemiplegia, or other paralysis, which was very suggestive of a tumor of the frontal lobes. Autopsy showed a glioma in the right hemisphere the size of a Tangerine orange. An exploratory operation did not reveal any tumor, but gave great relief to the headache and eye symptoms.

7. **Estimation of Urinary Ammonia.**—Harrower uses a graduated tube of glass. The test is made by filling the tube up to the 10 mark with the urine to be tested, and adding 3 drops of an indicator, in the form of 0.5 per cent. solution of phenolphthalein in 50 per cent. alcohol; then 3 or 4 grams of a potassium oxalate solution are added and the tube filled with water to the zero mark. The tube is closed, shaken and decinormal soda solution added up to a pink color. The total acidity is read off and marked down. Then 2 or 3 c.c. of dilute formalin solution are added. The pink color is discharged by the acids; and decinormal soda solution is again added till the pink color is again produced. Each cubic centimeter of decinormal soda solution represents 0.00068 grams of ammonia. The amount per cent. is obtained by multiplying by ten. The normal degree of urinary acidity fluctuates between 30 and 40 degrees.

8 The Medical Profession for 6,000 Years. J. J. Walsh, New York.
9 Peritoneal Adhesions. B. Robinson, Chicago.
10 Mind and its Relation to Heredity. C. F. Clowe, Schenectady, N. Y.
11 Tuberculosis of the Knee Joint. I. D. Steinhardt, New York.
12 *Pathology of Pseudohypertrophic Muscular Dystrophy. F. C. Potter, Philadelphia.
13 *Results of Treatment in 172 Cases of Pulmonary Tuberculosis in the Out-Patient Department of the German Hospital. G. L. Rohdenburg, New York.
14 *Blood Pressure in General Paresis. A. Schmiergeld, New York.

12. **Pseudohypertrophic Muscular Dystrophy.**—Potter reports a case which he believes supports the view held by others as well as by himself that there may be transitional forms of dystrophy in which alterations in the nervous system go hand in hand with diseases of the muscles. Pseudohypertrophic muscular dystrophy developed in a boy with no antecedent or family history early in life; and from the age of 9 until the time of his death at 15, he could not walk. At the time of death, resulting from pneumonia, there was inability to use the lower and to a less extent the upper limbs, hypertrophy with fatty infiltration of the calf and thigh muscles, protrusion of the abdomen, atrophy of the chest, shoulder and arm muscles, and a complete loss of reflexes.

Necropsy demonstrated typical changes in the peripheral muscles, smallness and degeneration of the peripheral nerves, diminution in the size and degeneration of the anterior roots with a degeneration and some disease of the cells of the anterior horns, most marked in the ventromesial group and in the cells of Clarke's column, especially of the lumbar cord. Besides there was a marked fatty infiltration in the liver with an hypertrophy, atrophy and fatty infiltration of the heart muscle with a slight fibrosis.

13. **Tuberculosis.**—Of 172 patients under treatment, 16 died, and are not taken into consideration, except in estimating the percentage of results. The cases were not selected, and Rohdenburg says that fully 25 per cent. of those patients now classed as improved will in another 12 months be placed either in the apparently cured or arrested class, if the present rate of progress is kept up. The results obtained in the various stages of the disease are as follows: All stages: Apparently cured, 3 (1.75 per cent.); arrested, 14 (8⅛ per cent.); improved, 65 (37⅝ per cent.); not improved, 74 (43 per cent.); died, 16 (9.05 per cent.). Cases in the first stage, 76: Apparently cured, 3; arrested, 8; improved, 43; not improved, 22. Cases in the second stage, 56: Apparently cured, 0; arrested, 6; improved, 20; not improved, 30. Cases in the third stage, 24: Apparently cured, 0; arrested, 0; improved, 2; not improved, 22.

14. **Blood Pressure in General Paresis.**—Schmiergeld found that the blood pressure in general paresis is very variable. In the majority of cases, however, it seemed to be lower than in normal individuals. There apparently exists no relationship between the mood of the paretic and the arterial tension; elated paretics may have a high pressure and depressed paretics a low one.

18 Studies in Psychopathology (continued). B. Sidis, Brookline, Mass.
19 Pregnancy, Uterine Myomata and Peritonitis. J. G. Mumford, and J. B. Hartwell, Boston.

17. **Work as a Therapeutic Factor.**—At the sanatorium at Rutland, a system of work has been in operation for several years. All patients who can exercise without symptoms are expected to work from half an hour to two hours daily. The work allotted to them is the making of beds, care of the wards, wiping the woodwork with damp cloths, carrying trays, serving lunches, picking up about the lawns and walks, running a lawn mower, etc. The lighter work is first given to the patients, and the heavier work, such as carrying trays and running the lawn mower, is given after they have demonstrated their ability to do the light work without reaction. The number of patients at present doing this grade of work is 132, or 38 per cent. of the whole number under treatment.

The ultimate results of exercise seem to be well exemplified by the subsequent history of those patients who worked while in the sanatorium and also played ball on the team, which for several years has been a feature at Rutland. The rather strenuous exercise in which these patients indulged, in addition to their work, afforded a pretty severe test of their physical condition. During the last five years, 27 patients were allowed to play on the ball team. All these men were working four and one-half hours and their exercise was not restricted. They were picked men, selected from the daily average population of 180 men. All had been under observation and sanatorium treatment for several weeks or months and had been worked up to this amount of exercise gradually. The disease was incipient in 12 and moderately advanced in 15.

Their condition on discharge from the sanatorium was as follows: Apparently cured, 3; arrested, 11; improved, 13; average duration of residence, eight months.

The subsequent history of these men showed that 22, or 81.4 per cent., are to-day doing fulltime work, 2 are working part of the time, but have had relapses, and 3 are dead. Of the latter, 2 resumed intemperate habits after leaving the sanatorium, and their early death was directly traceable to dissipation. One had a relapse after returning to work and died of a pulmonary hemorrhage.

The above facts are given, not in advocacy of baseball as a therapeutic agent, but simply to show that, in selected cases, pretty strenuous exercise can be allowed with safety and even with advantage to the patient in hardening him and building up his resistance.

32 *Pseudocyesis. H. E. Tuley, Louisville.
33 Double Suppurative Parotitis Following Salpingo-Oöphorectomy. J. H. Peak, Louisville.

22. Abstract of and comment on this article appears in the Department of Medical Economics, this issue.

32. **Pseudocyesis.**—Tuley reports the case of a woman, aged 54, married 25 years, who never conceived. Her last regular menstruation was in July, 1908. She missed in August, but menstruated on September 15, when due. This period lasted the full five days, but the amount was much less than usual. From this time there was no menstruation until January, 1909, when the flow lasted only part of a day and was very slight. This spotting was repeated in February for a part of a day. Early in October, morning sickness was noted, especially when brushing her teeth, this continuing until early in January. At no time was there vomiting. In January it became necessary to increase the size of her skirt bands, which were uncomfortably tight owing to increase in size. A noticeable tenderness of her breasts and an apparent enlargement were present at this time. Very shortly cravings for unusual articles of food were noticed and commented on by patients and friends. On Feb. 10, 1909, a faint flutter was noticed in the region of the pubes, which was thought to be quickening, but it was very indistinct, and it was not until February 12 that the movements could be felt and confirmed by the patient with the hand on the abdomen. This movement was continuous and often annoying to the patient when awake.

From this time until March 26 the "pregnancy" advanced normally, with gradually increasing enlargement of the abdomen. Tuley then saw the woman. Inspection of the abdomen revealed an enlargement extending midway to the ensiform cartilage, entirely symmetrical, and on palpation the abdomen was soft and no tumor could be felt. By vagina the uterus was found to be practically normal in size and in good position. The enlargement of the abdomen was entirely a gaseous distention of the intestines. Under restricted diet, daily high colon irrigations, saline cathartics once daily and lactic acid bacteria tablets three times a day, the abdominal distention disappeared. The patient returned home in ten days, having entirely recovered.

48. **Action of Iron and Cyanids on Oxidation.**—Mathews and Walker conclude their work on the oxidation of cystein with the following summary: The spontaneous oxidation of cystein to cystin is enormously accelerated by a very small amount of iron. In $\frac{M}{100,000}$ solution the oxidation is doubled. The acceleration involves a temporary union of the oxidized iron with cystein, forming a violet compound. The combination is probably with the sulphur of the cystein. The oxidation is accelerated also by gold, platinum, copper and mercury among the metals; and by arsenic among the metalloids. It is strongly retarded by lead, nickel, cobalt, uranium, thorium, zinc and cadmium. Cobalt inhibits more than nickel. These salts inhibit the accelerating action of the iron. The oxidation is not affected by medium amounts of manganese, barium, calcium, sodium or potassium salts. It is greatly reduced by concentrated barium chlorid solutions and by 4 molecular solutions of sodium, potassium and calcium chlorid solutions. In the particulars just noted, the spontaneous oxidation of cystein shows many interesting parallelisms to the oxidations of the cells.

50. **Neutrality of Tissues.**—According to Robertson's view, the proteins play a prominent rôle in the preservation of the neutral reaction of animal organs and fluids, since they are capable of absorbing a large amount of acid without materially affecting their reaction. The readiness with which the proteins combine with alkalies, expelling carbon dioxid from the bicarbonates, may explain the escape of carbon dioxid from the blood during respiration. The opinion of Henderson that "the importance of the proteins, through their alkali compounds, in the preservation of neutrality in true solution is surely secondary," is not justified, according to Robertson, by the facts described in his paper.

51. **Uricolysis and Uric-Acid Infarcts.**—The results of the work of Wells and Corper indicate that the human organism has power to form uric acid from other purins, but possesses no uricolytic power so that it can not destroy the acid once formed. The absence of uricolytic enzymes is demonstrated not only in the human fetus, but also in the organs of adults. The experiments of Schittenhelm indicated that the liver, kidney and muscle of the fetus were actively uricolytic, but Wells and Corper found the opposite to be the case. The uric-acid deposits in the kidneys of infants can not be explained by a tardy development of a uricolytic enzyme, but are probably due to the high proportion of uric acid in the urine of infants together with local conditons in the kidney which favor its deposition.

64 *Large Sliding Hernias of the Sigmoid. L. W. Hotchkiss, New York.
65 The Fat Appendix. H. A. Kelly, Baltimore.

59. **Jejunal Ulcer.**—One of the two cases reported by Paterson is of interest because it is the first case in which an attempt has been made to obtain an accurate analysis of the gastric contents, and of the fluid escaping from the jejunal fistula before and after operation for ulcer of the jejunum. The operation was an anterior gastrojejunostomy for pyloric stenosis with perforation of a jejunal ulcer five years later; resection of the affected portion of the jejunum, and anterior gastrojejunostomy "en-Y" ("Roux operation"). The patient recovered. Paterson also cites briefly 61 other cases recorded in the literature, a study of which shows that the risk of jejunal ulcer following gastrojejunostomy is probably under 2 per cent.

Clinically, there are two groups of cases: (1) Those in which perforation into the general peritoneal cavity ensues; (2) those in which general peritonitis is prevented by the formation of adhesions. Pathologically, the cases may be classified as follows: (1) Ulcers of the jejunum; (2) gastrojejunal ulcers, or ulcers at the site of the anastomosis.

Jejunal ulcers in some instances are of infective origin. In these cases ulceration commences within a very short interval after gastrojejunostomy, and usually the ulcers are multiple. In a large proportion of cases the ulcer is single, and is probably the result of the toxic action of hydrochloric acid, which injures the cells of the mucous membrane so that they are digested by the intestinal juice. Possibly other agents than hydrochloric acid may play a part in injuring the mucous membrane. Gastrojejunal ulcers are a direct consequence of the wound made in effecting the anastomosis, and their persistence is probably the result of hyperacidity of the gastric juice. Closure of a gastrojejunostomy opening is the consequence of cicatrization of a gastrojejunal ulcer. It is more likely to occur when the pylorus is patent, not because of the patency of the pylorus, but because in such cases hyperacidity is usually markedly present.

Any procedure or disease which diminishes the amount of bile and pancreatic juice in the jejunum favors the occurrence of jejunal and gastrojejunal ulcer. For this reason operations of the "Y" type and enteroanastomosis are inadvisable, at any rate in cases in which free hydrochloric acid is present in the gastric contents, as after these procedures the anastomosis and a portion of the jejunum are deprived of the protective influence of the alkaline bile and pancreatic juice. As no instance of ulcer after the posterior no-loop operation has yet been recorded, it must be assumed that its occurrence after this type of operation is less likely. It is possible, however, that this immunity is partly the result of improvements in technic, and in the after-treatment of gastric operations in general. In cases in which perforation into the general peritoneal cavity occurs, immediate laparotomy offers the only chance of saving the patient's life.

Inasmuch as there is some evidence that jejunal gastrojejunal ulcers may heal, an operation should not be performed in the chronic cases [illegible] after a thorough trial of medical treatment. Even wh[illegible] l inter[illegible]n is necessary, an attempt should first [illegible] dimi[illegible]cidity, if this be present. The aim [illegible] occurrence of this complication of g[illegible] treatment consists in (1) careful [illegible]nic, and (2) prolonged after-tre[illegible]on th[illegible] every case of recrudesce[illegible] gastrojejunostomy, espe[illegible]ity of hypersecretion, should be regarded as a case of potential ulcer and treated accordingly.

60. **Surgical Procedures for Tuberculosis.**—Pneumotomy with drainage of a tuberculous cavity was employed twice by Powers, in each case draining a cavity in a lower pulmonary lobe. In the first instance, a man, aged 42 years, suffered from a fairly large cavity in the left lower lobe. Costal resection was done and the pleuræ were found adherent; the lung was incised and the cavity entered at a depth of about 1½ inches; drainage. Improvement was but temporary, a sinus persisted and the patient succumbed to tuberculosis in a few months.

In the second case, a woman of 27 gave a history of pulmonary tuberculosis of six months' duration; she had lost in flesh and strength and had a purulent expectoration of 6 ounces daily. She was supposed to have an encapsulated empyema just below and within the angle of the right scapula. Costal resection showed that the pleuræ were adherent. Pleural separation discovered no pus. A needle thrust into the lung withdrew pus. An incision was made and a moderate cavity was entered at a depth of about one inch. Trabeculæ were broken down, gentle curettage was made; drainage was instituted. Bacteriologic investigation showed a mixed infection. This patient underwent a fairly speedy improvement. At the time of last report, one year after operation, the woman had gained materially in flesh and strength; expectoration was practically *nil*. A discharging sinus persisted.

62. **Treatment of Diffuse Septic Peritonitis.**—In three cases reported by Le Conte the essentials of the Murphy treatment were practiced: namely, a speedy operation; removal of the cause with the least possible traumatism to the peritoneal surface; no douching of the peritoneal cavity; the exaggerated Fowler position; and continuous enteroclysis by the drop method. In six other cases the peritoneal cavity was flushed with warm saline solution. The head of the bed was but slightly raised, the patients lying on the back or being turned on the right side, and salt solution was given by rectum—six fluid ounces every fourth hour.

In this series of nine cases there was but one death, which occurred on the fourteenth day after operation, probably from secondary infection of the liver, plus secondary hemorrhage. A postmortem examination was not allowed. In all instances the patients arrived in the hospital in such serious condition that they were at once transferred from the receiving ward into the operating room.

64. **Sliding Hernia of Sigmoid.**—In Hotchkiss' case the sac was large and reached well down into the scrotum. It contained omentum and small and large intestine. All the contents were easily reducible, through the wide internal ring, save a long piece of the sigmoid colon which was adherent by a short mesocolon to the posterior wall of the sac, to the extent of about four inches. Under these conditions it was, of course, impossible to close off the neck of the sac by any of the usual means of ligation or suture. The mesosigmoid being short, could not be tied off so as to permit the reduction of the gut without danger of causing necrosis. In order to overcome this difficulty, Hotchkiss constructed an elongated mesocolon from the tissues of the hernial sac wall in such a manner as to permit of the easy and perfect reduction of the gut into the abdominal cavity, and not to interfere with the suture of the internal opening of the sac. The steps of the operation are as follows:

Having freed the sac from the cord to its full extent, the sac is opened anteriorly and its reducible contents replaced within the abdomen, and held there by a gauze pad. The incision in the sac is then prolonged upward to the internal ring and downward nearly to the lowermost point of attachment of the mesosigmoid on its posterior wall, which permits easy eversion of the sac wall. Grasping the adherent sigmoid and pulling it gently forward, it will be found that the peritoneum of the split hernial sac will become everted in such a manner as easily to form a new and elongated mesentery for the sigmoid, with its smooth peritoneal surfaces turned outward to form its free surface, and its outer or non-peritoneal surfaces [illegible]lling in contact. Suturing the edges of this new mesentery [illegible]her permits its enlongation to an extent sufficient to allow the perfect reduction of the sigmoid into the abdominal cavity. When this step has been accomplished the somewhat irregular-shaped opening into the abdominal cavity may be sutured tightly by a purse-string suture introduced from within, or by any other form of suture which seems best to meet the case.

108 Fracture of the Skull. H. C. Rooth, Buffalo.

101. **Sufficiency of Standard Remedies.**—Standard remedies are those which measure up to the requirements approved by well-informed members of the profession. The Pharmacopeia is the highest standard for therapeutic agents. The large number of official substances—far exceeding the capacity of any man to know thoroughly and to use with skill—is presented under a great variety of forms to suit the most varied conditions. But the crucial question is to what extent does it include that which is really valuable in therapeutics. Many would be sadly handicapped by the loss of all unofficial remedies, but Hatcher believes the true explanation of this lies in the fact that we have permitted the proprietary interests to train us in the use of their products, until we have come to depend on them instead of familiarizing ourselves with official substances, and learning the possibilities afforded by the intelligent use of them. This crucial question can be answered correctly only when we have determined how many of the unofficial substances are indispensable even to one who is well acquainted with those which are official and is able to use them properly.

The stock argument of those who cling to the use of proprietary preparations and ready-made mixtures is that phenacetin and antifebrin were indispensable long before they became official. To cite these in support of the argument of the insufficiency of standard remedies is a confession of ignorance. They are the result of careful scientific investigations, the highest aim of therapeutics, but it is, indeed, a far cry from phenacetin to antikamnia. Every proprietary remedy is in the experimental stage, and physicians owe it to themselves and to their patients to disregard the literature gratuitously supplied by the manufacturers. Commercial men are not philanthropists; they are optimists and use the bright lexicon of youth which lacks a certain word with which their followers become all too familiar. Even in Germany, there are signs of awakening from the apathetic attitude toward this question, and protests are being made against the flood of fraudulent nostrums.

We do not need more new remedies which will save us the trouble of thinking, says Hatcher. The most urgent need in therapeutics to-day is the careful study of the best standard remedies which we now possess, for that man is recreant to his trust who accepts a fee from his patient and then trifles with that patient's health, while experimenting with secret remedies or those of which he knows little, and that little, often the mere statement of an irresponsible detail man who is hired to talk about that which he does not understand.

104. **Reform in Proprietary Medicines.**—Alsever says that many good men tell us that if we will confine our prescribing to U. S. P. and N. F. preparations we can accomplish more and have as elegant preparations as though we used proprietaries. The book entitled "New and Nonofficial Remedies," which contains descriptions of the remedies which have been accepted by the Council on Pharmacy and Chemistry of the A. M. A., gives reliable information regarding the remedies which since the last revision of the Pharmacopeia have seemed

to be of value. If we will confine ourselves to the drugs and preparations described in these three books we can not go far wrong. If we will decline to discuss with detail men remedies which do not bear a printed statement of their composition, and if we decline to use others unless they have been submitted to the Council for acceptance, we will not only keep our own skirts clear, but will also influence manufacturers to market only ethical goods. It is probably useless for a general practitioner to attempt to "try out" a new remedy. His observations will be so few and they will be made on people with such varying physical defects and modes of life that they will be valueless. If we can by individual and united efforts influence the medical, the religious and the daily papers to refuse medical advertisements which contain untruthful or grossly exaggerated statements, we will have accomplished a great good. It is our duty to the public to limit the use of secret remedies as much as possible.

110. **Wassermann and Noguchi Complement Fixation Test.**—Fox claims that of the different methods of serodiagnosis of syphilis depending on the principle of complement-fixation, that of Noguchi seems most perfect from a theoretic standpoint, and from the standpoint of simplicity in technic it stands without a rival. Fox states that his comparative analysis of the Wassermann and Noguchi tests shows, in cases of syphilis, a larger proportion of positive reactions with the Noguchi than with the Wassermann test.

114. **Ulcerative Stomatitis.**—Cushing reports cases to illustrate the association of a mildly contagious form of ulcerative stomatitis with the presence of Vincent's bacillus, i. e., with the symbiosis of *Bacillus fusiformis* and *Spirochæta dentium*. They occurred in institutions, in children from 3 to 8 years of age, all of whom suffered from malnutrition or ill-health, and there seemed to be a mild infectiousness about the disorder. The disease began as a small superficial ulcer at the margin of the gums and afterward extended in some cases in the form of an adherent false membrane or superficial necrosis to the mucous membrane of the cheek, the tongue or the fauces; there was a characteristic fetid odor, mild constitutional disturbance and enlargement of the neighboring lymph glands. Smears from the lesions showed the characteristic organisms in great numbers. All recovered in from one to three weeks. Potassium chlorate given internally seemed to hasten the recovery.

115. **Diphtheria of Intestines.**—McKechnie records an unusual case of dysentery. The patient was a girl, 6 years old, born in Fiji. The parents were on their way home to Germany, taking the child with them. Shortly before leaving Suva, the child was taken ill with what seemed a mild dysentery, and the condition persisted throughout the trip of two and a half weeks. On arrival at Vancouver, the child was emaciated and very much exhausted. The dysentery was fairly well held in check by the treatment the patient received on ship board, but she was having several small stools daily, stained with blood and consisting of mucus and pus. Some of the motions were of pure mucus—about half a pint at a time. Enormous quantities of streptococci were found in the stools. These rapidly disappeared under treatment with streptolytic serum, but the symptoms did not abate. Finally, cultures showed bacilli of the diphtheritic type. At once antidiphtheritic serum was used, with immediate improvement of the symptoms, and two days later a complete cylindrical cast of the bowel, about four inches in length, was passed. The child made a slow but uninterrupted recovery after this. The cast was examined microscopically, and proved to be a true diphtheritic membrane. It was noted that the patellar reflexes were absent. Later the patient developed paralysis of the anus, so that for a couple of weeks the bowels moved involuntarily.

126 Field of the Albany Red Cross in the Fight Against Tuberculosis. H. Van Rensselaer, Albany.
127 Review of Recent Work on the Pancreas. W. Tileston, Boston.

124. **The Insanity Defense for Crime.**—The prominent points presented by Chapin were suggested by participation as a witness or spectator in court, or by perusal of public reports. The important or dominating thoughts may be condensed as follows: He says that from common observation and experience, we recognize the fact that indulgence in passions may result in a loss of self-control and gradual degeneration which is acquired and not due necessarily to disease, inheritance or environment. If this is true of individuals, it is equally true that whole communities and even nations may degenerate to a low state or be destroyed from a lax administration of justice. Human and divine laws are intended to secure the preservation of social order and the betterment of a community. On their execution depends the security of human life. If self-preservation is a maximum or principle which may be a sufficient defense of the individual, in a larger sense self-preservation may be a warrant for a community to adopt extraordinary measures for its protection as well as for the prevention of crime. If persons actually insane have been convicted of capital crimes, which Chapin believes has been of rare occurrence, it has more frequently happened that crime committed in an exacerbation of some one of the human passions has been condoned mainly through a doubt of the sanity of the criminal, created by the evidence of medical witnesses who would not have felt warranted in signing a certificate of insanity for detention in a hospital, as no single symptom had been presented that antedated the criminal act.

In the opinion of some, the trial judges have freely opened the way to the introduction of extraneous issues; have permitted the introduction of highly technical questions, the use of scientific terms that do not imply necessarily advances in psychiatric knowledge, nor are universally accepted. It is admitted the names are new discoveries, unfamiliar, beyond the comprehension of the court and jury, in themselves having no significance, yet they have a mysterious influence, and work the court into a state of doubt or scientific indigestion. Chapin believes that insufficient attempts are made to differentiate the operation of the uncontrolled human passions from what we ordinarily understand to be the disease or condition we call insanity. Some amendment or change in the present practice of introducing the medical witness on the stand without bias or the suspicion of it would be welcomed, but it might be regarded as a gratuitous offer for a medical man to make suggestions about legal procedures that belong properly to the courts. The penologist must study whether it is possible that any modification of the penalties for crime can be made that would more justly recognize degrees of criminality.

134. **Active Bacterial Immunization.**—Thomas found by experimentation that bacterial immunization can be established in rabbits by inoculations of various bacterines. The immunity endures for a period, the duration of which is, as yet, undetermined, but then declines. The duration and degree of bacterial immunization by some bacterines or bacterial suspensions is more lasting than by others, notably, in this series, that by the suspension of the tubercle bacilli, although absolutely properly sized and spaced inoculations might nullify these differences. In the presence of a severe intercurrent infection, the opsonic content of the blood is markedly diminished.

135. **Typhoid Cutaneous Reaction.**—The typhoid cutaneous reaction is a simple test which can be applied by the physician at the bedside. It is free from danger, and, is, therefore, far superior to the ocular reaction. It yields a positive reaction in from fifteen to twenty hours, or less, without giving rise to any discomfort or annoyance to the patient. The reaction gave positive results in every case of typhoid fever in which it was tried by Deehan, and negative results in diseases other than typhoid fever.

1. **Double Filigree Operation.**—This method consists in strengthening the walls of the inguinal canal by the implantation of two filigrees of silver wire in the tissues in such a way that subsequent stretching or bulging is rendered impossible, and the necessity of a truss is entirely done away with. The filigrees are made in two sections—a pubic and an iliac section. The former is always made of the following dimensions: At the narrow end its width is 3/4 inch; at the wide end, 1½ inches, this being the usual length of the adult inguinal canal. Being constructed on the principle that every filigree, whether abdominal or inguinal, should be made with not fewer than eight loops to every inch of its midrib, this will give thirteen loops on either side of the pubic section of an inguinal filigree. The iliac section is made in such a way that its inner third corresponds in shape and size to the outer two-thirds of the pubic section. Its outer end must meet the requirements of the case, being trapezoid, square, or what is more usual, oblong, and of a total length of from 2½ to 3 inches, as may be found necessary. The wire must be unalloyed silver. These filigrees are so placed that the cord comes to be sandwiched, as it were, between two layers of filigree in the canal, the natural relations of which are hardly altered; and further, that the area external to the internal abdominal ring is fortified by a filigree of any size which may be deemed necessary.

5. **Sterilization of Skin.**—Stretton employs a modification of the method of skin sterilization with iodin, as used by Dr. A. Grossich of Fiume. He paints a wide area of the surface to be operated on with a 1 to 3 alcoholic iodin solution previous to the administration of the anesthetic. It is painted on very freely, especially over hairy parts, and allowed to soak in. It is again painted immediately preceding the operation. After the stitches are inserted they are painted over for a margin of an inch all round. The first and only dressing is usually made on the eighth day; the stitches are then removed, and the line of incision, with a margin of 1 inch, is painted with the iodin solution. If for any reason the wound requires to be inspected at an earlier date, it is painted as above described. No previous preparation of any kind is undertaken—no bath, no scrubbing and no shaving. The latter is an important point, because it saves the patient a good deal of after-discomfort. This is at variance with Grossich's method, and combined with the weaker solution of iodin constitutes the difference.

26 Tetanus Treated with Antitoxin. R. C. Pitt.

20. **Malformations of the Heart.**—In this paper Keith discusses transposition of the arterial stems; reversion of the heart; imperfect separation of aorta and pulmonary artery; patent ductus arteriosus; malformation of the semilunar valves; imperfect formation of septa; the foramen primum; and patent foramen ovale.

21. **Antityphoid Vaccines.**—Semple and Matson found that the sterilization of antityphoid vaccine can be accomplished efficiently by the addition of 0.5 per cent. carbolic acid. Heating a vaccine in order to sterilize it introduces a harmful and unnecessary element which acts in two ways: (1) It diminishes its immunizing properties, and (2) it curtails its keeping properties. In the experiments recorded the deleterious effects of heat are clearly shown. Antityphoid vaccine sterilized by the addition of 0.5 per cent. carbolic acid retains its immunizing properties unimpaired for two years at least. This is proved (1) by the fact that animals and men treated with a two-year-old vaccine prepared by this method showed the same blood changes as did those treated with a fresh vaccine similarly prepared; and (2) by the fact that animals treated with a two-year-old vaccine prepared by this method withstand the same amount of a virulent typhoid culture when given intra-

peritoneally as do those treated with a fresh vaccine similarly prepared. Animals inoculated with antityphoid vaccine sterilized by the addition of 0.5 per cent. carbolic acid attain a higher degree of immunity than similar animals inoculated with a vaccine sterilized by heat (60 C. for 20 minutes or 53 C. for one hour) and the subsequent addition of an antiseptic. An antityphoid vaccine sterilized by heating for 20 minutes at a temperature of 60 C., and the subsequent addition of 0.5 per cent. carbolic acid has considerably deteriorated after being kept for two years.

22. **Family Hematuria.**—The seven cases reported by Aitkin are of one family which has been under his observation during the past seven years. So far as the history goes, the family is comprised in all of 17 persons, of whom 10 have suffered from hematuria. Testimony is conflicting as to whether the great-grandmother had hematuria or not. She died at an advanced age from "senile decay" with dropsy. The great-grandfather was healthy. Their only child, a daughter, had hematuria (according to relatives), married and had eight children (seven sons and one daughter), and died aged 38 years from Addison's disease. Four of her sons died in infancy from an unknown cause; and one, aged 14 years, from an indefinite "brain trouble." There is no evidence of any of those having suffered from hematuria. The remaining three are alive. The eldest son, aged 31 years, has not had hematuria, but his six children have all been hematuric; the second son, aged 28 years, has suffered from hematuria, and his only child, aged 2 years, is also hematuric; and the daughter, aged 23, unmarried, is also hematuric. There is no history of hemophilia, nor is there any rheumatic tendency in the family. It is interesting to note that in this family the hematuria has been inherited, first, through the female side, and then on two occasions through the male side, in one case the transmitting male not being affected.

August 4

32 Rheumatoid Arthritis. W. P. Herringham.
33 *Popliteal Aneurism. H. M. Rigby.
34 Diseases of the Thyroid Gland. A. T. Davies.

28. **Mitral Stenosis in Childhood.**—The treatment of mitral stenosis in childhood is mainly the treatment of rheumatism. Warn the parents of the meaning of sore throats, fleeting pains, nervousness and chorea, feverishness and pallor. If possible get such children taken from damp, low-lying houses, and see that they are properly clothed and their extremities protected. Large unhealthy tonsils should be enucleated. Spring and autumn and particularly sudden damp cold after much heat, should be a signal for added watchfulness. Early symptoms should be promptly treated by rest and warmth, and the use of salicylate of soda.

31. **Exophthalmic Goiter and Diabetes.**—Murray's attention was drawn *to the relationship between the thyroid gland and* the pancreas by a group of four cases which came under his observation, in which exophthalmic goiter was accompanied or succeeded by a severe form of diabetes. One patient recovered from a typical attack of exophthalmic goiter, which was, however, followed by a severe form of pancreatic diabetes, to which she succumbed. The disappearance of the exophthalmic goiter was evidently due to the return of the thyroid to a normal condition, and is an interesting example of how complete this recovery of the gland may be. The diabetes was the result of the destruction of the islands of Langerhans. When a second patient first came under observation she was suffering from exophthalmic goiter without glucosuria, whereas three years later she had practically recovered from exophthalmic goiter, but was suffering from a severe form of diabetes. A third patient with exophthalmic goiter who apparently recovered relapsed on taking thyroid tablets, the second attack persisting and becoming complicated by the development of composite diabetes. The fourth case illustrates the development of diabetes nearly eleven years after the onset of exophthalmic goiter. In all these cases, one patient being a man and three women, severe diabetes developed at a variable interval after the disease had either subsided or decreasd considerably by the time the diabetes had declared itself.

33. **Popliteal Aneurism.**—Rigby reports two patients operated on by the obliterative method in which the results were all that could be desired.

35 *Piroplasma Bigeminum.* A. R. Wellington.
36 Fasciolidæ in the Pancreas. R. B. Low.
37 *Cholera. R. W. Burkitt.

37. **Cholera.**—Elsewhere Burkitt emphasizes the great value of a large injection of morphin in cholera immediately the disease is suspected. He now reports a number of cases of bad collapses in all of which from 2 to 10 pints of saline solution were infused intravenously. The pulse instead of being quite impalpable, became full, strong and quiet, being at its acme by the time 3 pints had been infused, whereas twenty minutes previously the heart was beating at a rate of from 140 to 170, as recognized by the stethoscope. The face became fuller, and the awful sunken look to a large extent disappeared. Restlessness became less, the intelligence became brighter, the skin became warm. Burkitt suggests that the poison of cholera attacks principally, or perhaps only, the vasomotor system, that the heart is not at fault, that the abdominal veins are holding most of the blood in the body, and that the treatment in this condition should be that of shock. He further noticed in a number of cases that if persons sleep after an injection of ½ or ⅓ grain of morphin their chances of recovery are good; that morphin does not induce sleep in those patients who are badly collapsed, but only stops the diarrhea and vomiting.

Heart, London

July

38 *Irregularities of the Mammalian Heart Observed under Aconitin and on Electric Stimulation. A. R. Cushny.
39 *Nodal Bradycardia. J. Mackenzie.
40 *Paroxysmal Tachycardia. T. Lewis.
41 *Measurement of Systolic Pressure in Man. L. Hill.

38. **Irregularities of the Heart.**—Under aconitin many forms of irregularity of the heart occur, but most of these may be reduced to certain types. These, according to Cushny, are the following: (1) Reversed rhythm, in which the impulse to contraction is generated in the ventricle and spreads upward to the auricle; (2) impaired conduction through the auriculoventricular bundle which may lead to partial or complete block in either direction; (3) alteration in the strength of the contractions in auricle and ventricle; (4) extrasystoles in auricle or ventricle which sometimes occur at regular intervals (continuous bigeminus); (5) sudden changes in the rhythm of the whole heart. Two or more of these types may be present simultaneously. Aconitin has a greater tendency to cause pulsus alternans than most other poisons, and this is ascribed to its production of exhaustion and of delayed recuperation of contractility. Other drugs may induce alternans in the damaged heart by increasing its irritability, and thus make demands which the contractility is unable to meet. Other forms of irregularity were observed by Cushny in unpoisoned hearts under the influence of cold and electric stimulation and are described.

39. **Nodal Bradycardia.**—Mackenzie found that the heart's action may start continuously from a place other than the normal starting place, and in the resultant rhythm the auricular systole no longer precedes the ventricular. This abnormal rhythm is provisionally called "nodal rhythm." The rate of the "nodal rhythm" is usually more frequent than the normal rate. Mackenzie describes a form of nodal rhythm of *infrequent* rate. This form of bradycardia may arise suddenly in a heart previously showing the normal rhythm, or it may arise in a heart previously showing the nodal rhythm with a rate more frequent than the normal. It may be quite regular or may show premature beats, or it may be continuously irregular with a tendency to long pauses. While related to the

more common forms of nodal rhythm, it may occur in a patient with a slight heart block.

40. **Paroxysmal Tachycardia.**—Lewis reports in detail the findings in a case of paroxysmal tachycardia of the variety in which the auricle is responsible for the ventricular beat. He points out that two forms of paroxysmal tachycardia are encountered; in one the sequence of contraction of the cardiac chambers is normal; in the other the auricle fails to contract at the usual instant in the cycle. In the first, or auricular form of the affection, extrasystoles occur, but their nature is different from the beats of the paroxysm. The rhythm of the paroxysm is one *sui generis*. The evidence is, on the whole, opposed to the view that the paroxysm is to be regarded as the result of altered central innervation. It is more rationally ascribed to an intrinsic change in the heart itself. It is probable that the rhythm between the paroxysms is the normal rhythm of the heart, and that the rhythm of the paroxysm is present during the paroxysm alone. Paroxysmal tachycardia (of a ventricular form) was readily produced experimentally by Lewis by ligation of the right coronary artery, and in this condition the dog's ventricle may beat at a rate of 400 a minute. The ventricles contract first and their contraction is followed by the auricular systole. Vagal stimulation, when the heart is in this condition, as a rule, slows or stops the auricle, while the ventricular rhythm continues unaltered.

41. **Arterial Blood Pressure.**—Hill shows by experiments that in reading systolic pressures there are two factors to take into account: (1) The actual maximal pressure of the cardiac output; (2) the conductance of the pressure wave by the artery. The force of the wave is damped down in soft arteries, as sound waves are damped by velvet. Blood-pressure readings should be taken, therefore, under uniform conditions, with patients lying horizontally, not emotionally excited, not after exercise, not after taking hot food, tea, coffee or alcohol, not after the hand and wrist have been warmed or chilled. Comparatively synchronous readings of hand and foot arteries, the effect on the readings of oscillating the pressure up and down, and the effect of local heat gives information as to the state of the arteries, the value of which will grow with extended clinical observation.

45 *Treatment c from the First. (Ostéomyélite arquis.
46 *Gonorrheal
47 *Bismuth I bismuthage des trajets fistuleux.) P. Mauclaire.

44. **General Anesthesia by Way of the Rectum.**—Legueu asserts that he has been able to eliminate the injurious factors in rectal etherization and states that its advantages are so great in operations on the face, mouth, neck and thorax that it deserves the preference in these cases. Irritation of the bowel, by the fumes of ether, can be avoided, he states, by blending the ether with oxygen, at body temperature, and preceding the application by a brief inhalation of ethyl bromid to relax the ileocecal valve. With this technic, general anesthesia by the way of the rectum is no more dangerous, he asserts, than by inhalation, unless the intestines are diseased. He uses a Y tube to convey the oxygen to the rectum, one branch conveying the oxygen alone, the other branch passing it through a flask of ether which thus mixes with the oxygen as it passes along, the two branches uniting in a single tube which conveys the mixture into the bowel. The oxygen and ether are rapidly absorbed by the bowel and there is no meteorism as when air is insufflated. He gives the details of experiments with 20 rabbits, 5 cats and 7 dogs to illustrate the harmlessness of this technic.

45. **Treatment of Osteomyelitis.**—Marquis calls attention to the panosteosis which inaugurates osteomyelitis chronic from the start, the Haversian canals, periosteal and medullary spaces all becoming ossified, without any acute stage. There is no necessity to sacrifice the limb; trephining will drain any possible collection of pus, and if the pain is not intense and if there are no signs of abscess or sequester it is best to temporize. The whole process may heal spontaneously, or if an abscess or sequester forms it can be treated as it develops. This form of chronic osteomyelitis is rare. He has found only a dozen cases on record besides the one he here records. The patient was a boy of 8, free from syphilis and tuberculosis, who began to limp, with some pain. The child was kept in bed for three months, but there was no improvement and the lower part of the femur became greatly enlarged, but without tenderness and with no symptoms on the part of the knee. The *x*-rays showed the compact tissue forming a cylinder nearly twice the circumference of the femur above. Treatment was restricted to rest; the patient is still under observation, but recovery occurred in the cases on record, with or without operative intervention.

46. **Gonorrheal Phlebitis.**—Zesas reports a case and commends immobilization in treatment, the limb being raised to control the edema. The patient was a man of 30 with chronic gonorrhea which had been rebellious to all measures for a year. The phlebitis developed suddenly after a long walk.

47. **Bismuth Paste for Fistulas.**—Mauclaire found the bismuth paste of the greatest use in defining the indications in a case of tuberculosis of the spine, and he commends it for all such cases when examination of the urine shows the integrity of the kidneys. This preliminary examination of the urine is especially necessary, he asserts, when there has been long suppuration.

49 Case of Meningococcus Septicemia without Meningitis. A. Netter.
50 *Outcome of Serotherapy in Sixty-eight Cases of Cerebrospinal Meningitis. Id.

50. **Serotherapy of Epidemic Meningitis.**—Netter shows the great improvement that has followed the introduction of serotherapy of epidemic cerebrospinal meningitis, the reduced mortality and duration of the disease and the lesser proportion of persisting disturbances. In one case he made twenty-two intraspinal injections and one intravenous injection before the grave disease with its three relapses was conquered. Discovery of the meningococcus on lumbar puncture gave the signal for renewed injection each time. He is convinced that certain other patients might have been saved finally if the serotherapy had been kept up more perseveringly.

57 First Phases of Defense of Connective Tissue against Experimental Tuberculous Infection. (Les premiers stades de la defense du tissu conjonctif contre sa tuberculisation expérimentale.) J. Renaut and G. Dubreuil.

52. **Tuberculosis of the Kidney.**—In the two typical cases described the syndrome seemed to be that of ordinary Bright's disease in every respect, and nothing suggested the old tuberculous kidney lesions revealed by the autopsy. The "closed" tuberculous lesions, cheesy changes, etc., coexisted with diffuse and severe lesions of non-specific chronic nephritis. Gallavardin does not deny that an "open" tuberculous process in the kidney might spontaneously change into a "closed" lesion, but thinks it more probable that in these cases there is an autonomous

form of renal tuberculosis primarily and definitely "closed." The patients were men of 57 and 60.

55. **Method of Opening Bladder or Ureter Through the Vagina.**—Rochet has opened up the bladder or ureter in three cases by a simple vaginal technic which excludes the possibility of development of a fistula while it allows ample access for extraction of a calculus or for other intervention. About 1 cm. back of the mouth of the urethra and below, a transverse incision, about 3.5 cm. long, is made through the vaginal mucosa and through this alone. Then with a grooved sound the mucosa is worked free from the urethra above and then from the bladder. This mobilization of the mucosa is easily done, and it can then be pushed back to permit ample access to the bladder and ureter.

He concludes that calcium salts have a promising future in treatment of thyroid insufficiency.

Revue de Chirurgie, Paris

August, XXIX, No. 8, pp. 253-412

64 *Rational Treatment of Fractures of the Base of the Skull E. Vincent.
65 *Partial Atrophy of the Optic Nerve in Fractures of Base of Skull. A. Cantonnet.
66 Indications and Operative Results in Abdominal Injuries from Small Bullets. (Plaies pénétrantes de l'abdomen par petits projectiles de guerre.) J. Poche.
67 *Tumors of the Spermatic Cord (Tumeurs du cordon spermatique.) M. Patel and A. Chalier. Commenced in No. 1.

64. **Fracture of Base of the Skull.**—Vincent is convinced that the only rational treatment of fracture of the base of the skull is to forestall the development of meningitic disturbances, opening a way for the escape of infectious agents and their toxic products, without waiting for them to make their influence felt on the meninges. In most cases the fracture communicates with the exterior by openings into the cavities in the face or the petrous bone, but attempts to disinfect by rinsing and spraying through these cavities have always proved ineffectual. After symptoms of meningitis have developed, it is then too late to arrest the fatal progress of the infectious accidents. Treatment should forestall them, and this is possible by trephining at once, leaving a permanent opening for the escape of the cerebrospinal fluid. There is thus no retention and no cultivation of the microbes in a closed cavity to enhance their virulence. Both microbes and toxins are eliminated as soon as they develop, and this is the rational treatment of all serous membranes when infection threatens or is installed. Repeated lumbar puncture is useful in aiding the elimination of the infectious products. Cushing's subtemporal trephining answers the same purpose as lumbar puncture, but has a more rapid and energetic action, although Cushing does not recommend it for more than the relief of compression. Vincent reports two cases in which it answered its purpose admirably. He trephined as near the fracture as possible, incising the dura mater to expose the surface of the brain over the entire extent of the opening in the bone, then introducing a drain down to the brain and suturing the skin around it. He kept up the drainage for about two weeks and the patient in his first case recovered without a sign of meningitis, although the tympanic membrane and Eustachian tube had been torn by the accident, as evidenced by the bleeding from both, and the fractured parts gaped considerably. The patient was a man of 60. The results at first were equally good in the second case, but lack of care later, after removal of the drain, permitted tardy infection after the patient was supposed to have been cured. In this case thirty hours had elapsed after the accident before the wound was taken care of. With the Cushing subtemporal decompressive technic the trephining is done in the temporal region, where the bone is thinnest; the temporal muscle is merely pushed aside, not severed. In case of rupture of the meningeal artery or one of its branches the extradural clot is reached at once and the artery can be easily ligated. In most cases of fracture of the base of the skull the point of the temporal and the base of the frontal lobe are most liable to be injured, and the subdural effusion resulting is most readily drained by this technic, as also the edema resulting from the contusion of the brain. In conclusion, he adds that this intervention reduces materially the number of complications, especially traumatic neuroses, which are so frequent in these cases of bursting fracture of the skull healing without operative intervention.

65. **Partial Atrophy of the Optic Nerve After Fracture of the Base of the Skull.**—Cantonnet states that in 268 cases on record the injury of the visual apparatus from fracture of the base of the skull involved the optic nerve close to or in the optic canal in all but 43 cases. The lesions were bilateral in 17 cases, and they entirely retrogressed in 6 of these and in 4 of the 208 unilateral cases. In 2 cases personally observed the atrophy was only partial on one side. The injury of the optic nerve is generally due to a fissure of the optic canal; vision, though totally lost at first, may gradually return. It is necessary to wait for some time before deciding as to the outcome; blindness coming on after the accident may subside partially or entirely in time, and, on the other hand, after an interval of normal vision blindness may become installed later. His first patient was a man of 60; after a fall from a horse unconsciousness for half an hour and blindness in the left eye with defective vision in the right were the only signs of fracture of the base of the skull. Vision gradually improved in the right eye by the end of a year and is now 1/6 normal. In the second case a physician hit the left orbit against a ladder; there was no unconsciousness, merely a little dizziness, but the eye was apparently totally blind thereafter for two weeks, after which vision in this eye began to improve and by the twenty-fifth day had recuperated all that was possible, and there has been no change since. The partial optic atrophy in this case affects only the maculary fibers, the peripheral fibers being still intact.

67. **Tumors of the Spermatic Cord.**—Patel and Chalier here conclude their long study of this subject with summaries of 110 cases.

Semaine Médicale, Paris

July 28, XXIX, No. 30, pp. 349-360

68 *Pupil Sign of Aortic Insufficiency: Circulatory Hippus. M. Landolfi.

August 4, No. 31, pp. 361-372

69 *Indications for Use of Electricity in Ileus. (Le lavement électrique dans l'iléus.) F. Lejars.

68. **Pupil Sign of Aortic Insufficiency.**—Landolfi announces that in pure aortic insufficiency, free from other valvular lesions and aneurism there is sometimes a true hippus, that is, the iris contracts and dilates synchronous with the heart beat, contracting with the systole and dilating with the diastole. He found this sign marked in one of the 24 patients with aortic insufficiency examined, and later was able to elicit it in three more after giving fifteen drops of digitalis a day for four days. It seems to be the equivalent of Corrigan's pulse and the other signs of aortic insufficiency, but, unlike them, it seems to be strictly limited to well-compensated, pure aortic insufficiency. It is merely an exaggeration of the physiologic cardiovascular hippus in the peripheral vessels and iris. The "circulatory hippus" was observed also in a dog with experimental aortic insufficiency, when heart stimulants were given.

69. **Electrical Treatment of Ileus.**—Lejars occasionally has witnessed good effects from application of electricity in ileus, and thinks that this method should be a routine measure in hospitals, at least. When the occlusion is incomplete, and the result of prolonged constipation, electricity, applied early, is

an important aid in treatment. But in occlusion from cancer it should be used with great caution. Complete ileus contraindicates more than a single test application of the electricity, the physician being ready to proceed with a laparotomy at need. Whenever there is a suspicion of appendicitis or peritonitis electrical treatment is strictly contraindicated and dangerous. Under other conditions, if applied gently, with a medium current and without too frequent interruptions, it is not dangerous in itself, but may become so if too prolonged or too often repeated. He refers especially to the method introduced by Boudet of Paris twenty years ago.

70. Operation for Uterine Prolapse.—Heidenhain gives an illustrated description of the stretching apart of the cleft between the levator ani muscles in childbirth, of the resulting incompetency of the supporting floor of the pelvis, and the means to remedy it by closing up the stretched cleft to restore normal conditions.

71. Connection Between Suprarenals and Sexual Characteristics.—The case reported with illustrations by Bortz differs from others on record, as the patient was not a hermaphrodite, but an apparently normal girl of 16 who had been menstruating for a year. Menstruation suddenly ceased then and a full growth of beard and hair on the body followed, while the voice changed to a more masculine tone. Otherwise the girl was feminine in appearance. She soon succumbed to an intercurrent phlegmonous affection following several felons, and the suprarenals were found enlarged and degenerated, actual suprarenal struma in both, while the ovaries were atrophied.

72. Operative Treatment of Extensive Hernia of the Linea Alba.—Henkel remarks that the choice of an anesthetic is of great importance, as a tendency to vomit strains the wound too much; he prefers lumbar spinal anesthesia for the purpose. Good results are obtained with a technic which makes a thick pad over the linea alba where the tissues are liable to be very thin in old neglected cases of hernia at this point. He incises the skin and fat tissue horizontally and turns it back, above and below, to allow space for an oval incision through the fascia. The edges of this oval incision are then drawn together and sutured, pushing inside all the tissue between. The muscles are then drawn together and sutured, then the fascia and finally the transverse skin wound. He claims a number of advantages for this technic.

76. Retrospect and Outlook in Treatment of Contracted Pelvis.—This communication from the maternity at Breslau, of which Baum is director, reviews the experiences with 1,301 cases of contracted pelvis encountered among 11,126 parturients in ten years. Premature delivery was induced systematically in 23.9 per cent. of 1,011 cases of contracted pelvis; 54.2 per cent. of the women were spontaneously delivered at term; perforation was required in 1.2 per cent.; high forceps in 3.7 per cent.; Cesarean section in 1.7 per cent.; pubiotomy in 2.4 per cent. and prophylactic version was attempted only in 0.7 per cent. The mortality of the children was 18.8 per cent., including 20 children delivered spontaneously. Scheffzek discusses the indications and results, his final conclusions being that the general practitioner must be trained in methods of artificial premature delivery, prophylactic version and high forceps—and should be ready to apply them at need in the home when it is impossible for him to convince the parturient or the family that the ideal management of contracted pelvis is the expectant supervision possible in an institution with all in readiness for operative delivery if demanded. The former methods are not the ideal, but they are the best possible in the home, and give fairly good results.

85 *Cancer Statistics. (Zur Karzinomstatistik.) L. Seitz.

83. Multiple Carcinomas.—Tsuji reports the case of a woman of 58 with a carcinoma of the uterine cervix, a second at the mouth of the urethra and a third on the nostril. In connection with this case he reviews the cases of multiple carcinoma in the literature.

85. Permanent Cures of Cancer.—Seitz reports from Döderlein's clinic at Munich 1,044 cases of carcinoma during the last twenty years. The operability averaged only 20 per cent., and thus only 221 radical operations were performed. Only 3.8 per cent. of the 850 patients with carcinoma of the cervix and 30 per cent. of the 20 with carcinoma of the body of the uterus have been permanently cured. In the latter group 6 of the 10 patients operated on have been free from recurrence for more than 5 years. Only 8 have been permanently cured of the 46 radically operated on out of the 475 cases of carcinoma of the uterine cervix, and 24 of the 90 operated on of the 375 patients with carcinoma of the vaginal portion of the uterus. The permanent cures are thus 36 per cent. and the absolute cures 6.8 per cent. in this latter group, while in the cervix group the figures are 27 per cent. permanent cures and 1.75 per cent. absolute cures.

94 Stereoscopic Roentgen Lantern Slides. (Projektion von stereoskopische Röntgenbildern.) M. Levy-Dorn.

90. Abdominal Phenomena with Incipient Pneumonia.—Glaserfeld has encountered two cases in which the syndrome deceptively simulated appendicitis but in a few days the abdominal symptoms subsided as severe pneumonia became installed. In one of the cases there was an interval of nine days before the symptoms of pneumonia became manifest. In both these cases and in 13 of 21 reported by Bennecke the pneumonia terminated in an abscess or other serious complication. The necessity for differentiating these cases of "pneumogenic abdominal shock" from actual appendicitis is beyond question, as a useless appendicectomy would weaken the pneumonia patient. The most important points in differentiation are: (1) the expression of the face, which is not so distressed as in appendicitis; (2) the tongue, which is generally moist and not much coated; (3) the rapid breathing; (4) the rigidity of the abdominal wall, which is never so circumscribed as in beginning appendicitis; the abdomen is only superficially tender, deep pressure is not particularly painful; (5) careful objective examination of the chest, regardless of the assumed appendicitis. Differentiation may be rendered much more difficult by drugs previously given. In his first case the patient was subject to lead colic and opium was given at first, which masked the diagnosis for a time. It is probable that the pain caused by the inflammation in the lung is reflected into the abdomen. The irritation may even be transmitted through the sympathetic nervous system to the splanchnic nerves, inducing tympanites.

91. **Diabetic Lipemia.**—Adler reports two cases which show that the lipemia is due to cholesterin and not to lecithin.

92. **Diagnosis and Treatment of Rectal Lesions.**—Rosenberg has obtained excellent results in treatment of proctitis and sigmoiditis by application of a powder after thorough rinsing. The powder is a mixture of from 15 to 30 parts tannin to 100 parts magnesia usta, to which some disinfectant may be added. He insufflates the powder through a long tube commencing at the upper part and powdering downward. He also gives an illustrated description of an instrument for dilating strictures, spreading concentrically the 5 or 6 stout branches by a gradulated thumb screw.

93. **Morbid Blushing.**—Aronsohn has found that persons addicted to excessive blushing are diffident, anxious to appear different from what they really are, and that the tendency to morbid blushing can be overcome by urging them to be more natural and true. He has always been able to cure it by moral suasion supplemented by a little hypnotic suggestion to inspire the patient with courage and decision.

July 30, XII, No. 13, pp. 481-528

95 *Latest Methods of Treating Inoperable Cancers. (Neuere Behandlungsmethoden bei inoperablen Krebsgeschwülsten.) K. H. Schirmer. Commenced in No. 8.
96 *Persistence of Thymus and Thymus Hyperplasia. C. Hart. Commenced in No. 9.

95. **Treatment of Inoperable Cancer.**—Schirmer reviews critically 245 articles in recent literature on the treatment of inoperable cancer, especially with radium, fulguration, serum (toxin) and trypsin. Czerny has applied fulguration in 59 cases and states that it accomplishes in half an hour more than Roentgen or radium treatment in three months. The wounds are very painful and sometimes the fulguration seems to stimulate the tumor to grow. He has never seen enlarged glands retrogress under its influence, and it has only a slight action at a distance. Moore's experiments have shown that scraps from a mouse tumor retain their vitality after immersion in liquefied air for from twenty to thirty minutes, thus resisting a temperature said to kill all germs and bacteria. This experience speaks against a parasitic origin of cancer. In order to obtain a correct opinion of the efficacy of the different methods of treating inoperable cancer, the experiences should be published with all details, body weight, blood picture, local details of the tumor, subjective findings, etc., with records of the duration, intervals and dosage of the measures used. The future seems to lie in a combination or mixture of the various measures, to attack the cancer from all sides, with local and general measures, internal and external. Podwyssotzki explains cancer as a battle between the younger and older cells, the younger devouring the older, and our aim should be to promote this autophagism for which he recommends potassium iodid, arsenic, alien serum, tuberculin and radium, to which list Schwartz adds the *x*-rays as one of the most effectual measures. In conclusion Schirmer calls attention to the central office at Berlin of the International Cancer Research Association which offers to supply data and information on request in regard to the experiences to date with any of the methods of treating cancer in vogue. One of the statutes of the association states that it is to be an international information bureau for all questions affecting cancer research.

96. **The Thymus.**—Hart concludes his critical review of 158 articles in recent literature on the anatomy, pathology and physiology of the thymus and records of cases of "thymus death," with the statements that the thymus must be regarded as an epithelial organ and probably as an organ with an internal secretion. It seems evident that an excess rather than a deficiency of thymus tissue and its metabolic products is injurious for the organism. It is possible, although not proved, that the death of new-born infants in asphyxia is "thymus death." The mechanical thymus death is usually due to a combination of several factors. The results of excessive thymus functioning are an autointoxication with a special harmful influence on the innervation of the heart which explains the sudden deaths in which the thymus is found much enlarged. The recent publications on the frequency of persisting large thymus in exophthalmic goiter *demonstrate that the thymus is an important injurious factor in these cases and explains the postoperative heart failure of patients with exophthalmic goiter.* The abnormally increased and perhaps perverted internal secretion of the persisting and enlarged thymus is responsible for the instability of the heart which causes it to break down at even slight extra demands on it. He is inclined to recommend surgical intervention in case of symptoms of "hyperthymization" without waiting for severe disturbances. Mere tracheotomy does no good; the gland must be partially or totally removed or space made for it by partial resection of the manubrium. Persistence and hyperplasia of the thymus are of the *greatest importance for the surgeon; the discovery of a persisting thymus in an adult should contraindicate general anesthesia, especially with chloroform.* Exophthalmic goiter should forbid any operation unless the thymus is previously removed. There does not seem to be much prospect of relief from Roentgen-ray exposures as they seem to act only on lymphadenoid tissue.

97. **Opsonic Index in Typhoid Bacilli Carriers.**—Gaehtgens has found that the opsonic index returns to normal in a few months after typhoid, unless the persons become chronic bacilli-carriers, in which case the opsonic index persists high.

98. **Hemolysis with Special Reference to Cancer.**—Richartz reports negative findings in 112 normal individuals and in 103 with various bronchial, kidney, joint, gastrointestinal and other affections, syphilis and benign tumors, while in 73 cases of malignant tumors hemolysis was pronounced in 46 per cent., as also in 52 per cent. of 40 cases of tuberculosis. He compares his findings with those of Crile. *His conclusions are* that under certain circumstances hemolysis may be of differential importance for the diagnosis of gastrointestinal cancer. Benign stenosis, peptic ulcer, nervous dyspepsia and chronic gastritis are not accompanied by hemolysis. He regards the isolytic element in the serum as a reaction of the organism to the destruction of the red corpuscles by the toxic products of the cancer or tuberculosis.

99. **The "Remains Test" in Stomach Lesions.**—Grandauer has applied the principle of the food-remains test to detect ulceration or excessive secretion in the stomach. *In normal conditions the smooth surface of the stomach lining allows it to be* completely emptied, but when the surface is ulcerated or covered with tenacious mucus, particles cling to it. In order to test this he gives the patient at night 2 gm. (30 grs.) of bismuth. The next morning he takes a fat-zwieback test breakfast, and an hour later the stomach content is siphoned out; the stomach is then rinsed out with 100 c.c. of water, and then it is rinsed again until the fluid is completely clear. This test applied to 64 persons proved a reliable index for ulcer or severe catarrh, and in the absence of the latter sustained the assumption of gastric ulcer when large amounts of bismuth were found in the rinsing water. This pathologic retention of bismuth does not occur in the absence of ulcer except with pronounced catarrhal gastritis.

100. Congenital Megacolon.—Sommer's case was distinguished by the sudden onset of the signs of trouble which had remained comparatively latent until the age of 13. The results of the technic used commend it to others. An artificial anus was made into the cecum; two weeks later a median laparotomy disclosed the enormous sigmoid flexure. A small incision was then made into the left groin, through which the sigmoid loop was pushed and sutured to the abdominal wall. The median incision was then sutured, and two days later the sigmoid loop was resected. The preliminary bringing out of the loop proved an important aid for rapid healing after the resection.

103. Functional Independence of Mammary Glands and Stimulation of Function by Sucking.—Cramer ascribes great importance to sucking of the nipple as the main factor in setting up the mammary secretion, and reports a number of cases which confirm his assumption that the mammary gland is to a certain extent independent of the other organs of the genital apparatus and that it can be stimulated to secrete milk, even before the termination of the pregnancy, by letting a child suck the breast. There is certainly some factor in a pregnancy which inhibits the secretion of milk; even in twin births the milk does not "come" until after the birth of the second twin, although a considerable interval may elapse between the births. As it is so important for the new-born animal to have its mother's milk, Nature compels the already born to seek their food elsewhere as soon as the mother becomes gravid again. But at the same time systematic sucking will install the mammary secretion and counteract this inhibiting tendency. Mothers can leave their infants for weeks at a time and then be able to suckle them on their return. Cramer mentioned a case of the kind in which two three-week intermissions on account of operations did not interfere with resumption of the child's nursing on the mother's return home.

110. Relations Between Lecithin, Cholesterin and Other Lipoids and the Action of Drugs.—Meyer ascribes anesthesia to the physical change in the conditions of the cell lipoids. The lipoid-dissolving anesthetics cause a change in the entire makeup of the protoplasm. His communication, read at the recent International Congress for Applied Chemistry, presents evidence to sustain this view. It explains why the effects of anesthetics vanish as the unstable, reversible combination, dependent on the tension of the anesthetic, is broken up. It is thus evident that the cell lipoids are essential vital elements of the protoplasm.

121 *Relations between Nose and Other Organs of the Body. (Beziehungen der Nase zu anderen Organen des Körpers.) B. Goldschmidt.
122 Direct Inspection of Pharyngeal Region. (Meso- und Hypopharyngoskopie.) F. Schilling.

119. Disturbances from the Milk in Breast-Fed Infants.—Finkelstein admits the possibility that a woman's milk might be toxic, but is convinced that this is the very rarest exception. He protests against the assumption current among the laity and some physicians that if a child is not thriving it is because the mother's milk is not good. In nearly every instance the indigestion ascribed to the composition of the milk is the result of an undersupply or, more frequently, to an oversupply. When this factor can be eliminated, if a child is not thriving on breast milk, there is some constitutional anomaly interfering with the proper digestion of the breast milk. The indigestion occurs entirely independent of the amount of milk ingested, and seems to be the result of a peculiarly irritable condition of the stomach, the manifestation of a neuropathic predisposition. All the children in the family are liable to display this same tendency to digestive disturbances on breast milk, and the history of the family generally contains records of tics, migraine, nervous headache, neurasthenia, hysteria, universal tendency to gastroptosis, enteroptosis, etc., or Stiller's universal asthenia. Examination of the infant will generally reveal some of these stigmata, and children who have dyspepsia on breast milk generally grow up lean and nervous, usually bright, but inclined to nervous dyspepsia, overexcitable vasomotor system, etc. He calls attention further to the fact that the stools may have an abnormal appearance while still the child is thriving. Determination of phosphates in the urine is a much more reliable sign of something wrong than the aspect and consistency of the stools, as the slightest disturbance in health is revealed by the appearance of phosphates in the urine. In practice, however, if the child is not being fed too little or too much, and its weight is duly increasing, the mother can be reassured even if the stools are abnormal. There is no need to torment the child with drugs or change to a wet-nurse—these first render actual the dreaded disturbance. The syndrome of indigestion in breast-fed infants corresponds to that in bottle-fed infants on mixtures containing considerable fat and sugar with little salt and casein. The neuropathic indigestion is generally observed early; if the child gets past the first weeks without it, there need be no fear of it later. When it develops it continues about the same for several weeks and then gradually improves or it may persist for a number of months. No drugs give any relief, but the dyspepsia of breast-fed infants is cured promptly when they are put on a mixture of cow's milk. The restless, crying, weakly infant begins to thrive at once after this change to cow's milk, the complete change in the gastric chemistry evidently providing better conditions for the oversensitive organ. In his practice he tries to ward off this resort to cow's milk as long as possible. Buttermilk, sweetened, or skim milk is the best substitute for a certain proportion of breast feeding, especially when the tendency is toward restlessness and colic. He is generally able to accomplish the desired result with three breast and three cow's milk feedings, even in the most serious cases, satisfied if the infant is sleeping well and increasing in weight, and paying no attention to the aspect and consistency of the stools. In his experience the children did not show marked progress until they were taking from 100 to 120 calories; some children required surprisingly large amounts on this mixed feeding. Whether this extra demand was due to the extra exercise of the restless children or to loss of energy from increased fermentation or was merely a peculiarity special to the existing constitutional anomaly, is a mystery. He has never found it necessary to wean the infant completely, although in two cases this was warded off only by a change of scene, the mother taking the infant into the country—another argument in favor of the nervous origin of the indigestion in these cases. He emphasizes the necessity for studying with special care all such cases of indigestion in breast-fed infants and the prompt and certain means of treating them, as otherwise the children are liable to be allowed to suffer needlessly, and confidence in the superiority of breast nursing may be shaken.

121. **Nerve Connections Between the Nose and Other Organs of the Body.**—Goldschmidt calls attention anew to the close connection between the nose and certain other organs, and relates a number of striking instances of complete cure—by cauterization of certain points in the nose—of pain in the stomach, genitalia, in regions innervated by the lower spinal nerves and in the head and face. His experiences confirm the assertions of Fliess in regard to the close relation between the nose and sexual organs, but he thinks that other organs are involved with equal frequency. He has not been able to find any special point in the nose connected with the various organs, but, as a rule, when relief follows application of cocain to any part of the nose, a permanent cure is obtained by cauterizing the spot with trichloracetic acid. He cites a number of instructive examples of each type. Nearly all the patients had applied merely for some nasal affection, and the discovery of the other trouble was a casual incident. In one case a woman of 30, being treated for a slight throat trouble, casually mentioned that she had had repeated gall-stone colics for seven years but had never passed any gall-stones and no treatment had been able to ward off the attacks which utterly prostrated her. He applied a cocain tampon to the outer end of the left middle turbinate during an attack and the pain was reduced in a few minutes. He cauterized the spot later and the patient was free from pain for a long time; then the colic recurred, on which he resected the part of the turbinate involved and also cocainized the outer end of both inferior turbinates and there has been no recurrence of the colic since. In another case a medical student, 28 years old, had suffered for ten years from vomiting, nausea and intense pain in the stomach after every meal, and had been under the treatment of many internists, in turn, without the slightest relief. After cocainization of the outer end of the middle turbinates the sensation of oppression in the stomach vanished. These points were then cauterized and the patient was told to eat anything he chose; notwithstanding a hearty diet there was no recurrence of pain or nausea until after the scab had dropped off, when the bone was resected and the outer end of the left inferior cauterized, since which there has been no further disturbance, the patient having been entirely cured for nearly two years. In another similar case the patient was not told that the little operation on the nose had anything to do with the stomach trouble, so that suggestion had nothing to do with the prompt and permanent cure. Cocainization of the nasal mucosa also proved effectual in curing subjective auditory and visual symptoms, and neuralgia in the face—the temporary breaking of the reflex arc evidently having a remarkably favorable influence on the disturbance. Migraine, he states, is of nasal origin in many cases, the progress of rhinology having explained it as a reflex from the nose. He warns that the nose is too important for heedless operations, while its intimate connection with so many vital organs deserves careful study.

125 Behavior of Appendix i [illegible] halten des Wurmfortsatzes bei [illegible]
126 Complement-Binding St [illegible] Laub and J. Novotny.

124. **Movable Viscera as Sign of Predisposition to Enteroptosis.**—Hausmann has been making a special study of deep palpation of the intestines and states that Stiller's congenital universal asthenia is revealed by discovery of a palpable and movable pylorus, unusually low location of the greater curvature of the stomach and of the transverse colon or a movable cecum and sigmoid flexure. When the greater curvature is only 1 or 2 cm. above the umbilicus, as the patient reclines, this indicates ptosis and is an unmistakable sign of constitutional asthenia. He is convinced of the importance of the floating tenth rib as a sign of constitutional asthenia, and advocates rejection of recruits with this finding as unfit for military service; a movable cecum and palpable pylorus are similar stigmata. In 300 persons examined the cecum was movable in 22 and all had the floating tenth rib with other signs of constitutional asthenia.

127. **Prophylaxis of Postoperative and Other Forms of Ileus.**—Heile makes a point of stimulating peristalsis in all cases of diffuse peritonitis, etc., by injecting from 50 to 100 c.c. of warm castor oil directly into a high loop of the small intestine before closing the abdomen. A silk draw thread closes the small hole made by the needle in injecting the castor oil. It seems to work more effectively if emulsified with a little soda and water. He has had 30 very severe cases among 250 of peritonitis in recent years, and 5 died of the 20 treated without the castor oil while only 1 died of the 10 receiving the oil, and the one fatality was in a patient practically moribund when operated on. He uses a special syringe which allows aspiration of bowel content before injection of the oil.

137 Influence of [illegible] ital Determination of Sex [illegible] M. Fraenkel.

133. **Mode of Diffusion of Anesthetic in Spinal Anesthesia.**—Gauss reiterates that the anesthetic spreads upward only according to the specific gravity of the solution. A solution with a high specific gravity, if the patient is seated, remains localized in the lower part of the subarachnoid space, while the cerebrospinal fluid above does not contain any of it. On the other hand, with a low specific gravity the anesthetic solution spreads rapidly throughout the fluid to the upper thoracic vertebræ which seem to be the top of the column of water, the fluid above being connected with the subarachnoid space in the brain only by capillary interstices, without any solid body of fluid. He states further that the anesthetic introduced is rapidly taken up by the spinal cord, so that the cerebrospinal fluid, even as soon as five minutes after the injection, contains scarcely any of the anesthetic, but after death the nerve substance yields up the alkaloid again so that postmortem the entire amount may be found in the cerebrospinal fluid. The results in experiments on animals can not be applied to man, as the dog has only about 6 c.c. of cerebrospinal fluid throughout the entire subarachnoid space; in the monkey the fluid is so scanty and the spinal cord fills the canal so closely that the injected fluid from lack of space is forced into the upper parts of the canal from purely mechanical reasons. If the patient remains sitting up for four or five minutes after the injection in the arachnoid space the anesthetic is taken up by the spinal cord and the individual can then recline, with the pelvis raised, without fear of spreading the anesthetic above the desired point. The high or low location of the field of operation should determine whether a solution with a low or high specific gravity is to be used. Gauss adds that he has applied spinal anesthesia in a continuous series of 1,500 cases without a mishap, the few observed in a preceding series of 300 cases being evidently due to the imperfections of the early technic.

134. Local Anesthesia for Operations on the Female Genitalia.—Wernitz reports 300 cases of abortion requiring curetting in which favorable results were obtained with local injection of a 1 or 2 per cent. solution of cocain representing from 0.02 to 0.04 gm. (5/16 to 10/16 grs.) of cocain. The anesthesia lasted for about 25 minutes and no mishaps were observed in any case, although general phenomena were observed—the ordinary symptoms of the action of cocain, not of intoxication. The injections can be repeated at need, he says, no cumulative effect or special after-effect having been observed in any instance.

135. New Technic for Hysterectomy for Cancer.—Zweifel found that peritonitis was responsible for the death in the large majority of the fatalities in the operations for uterine cancer at the Leipsic clinic, and consequently he has been devoting special attention to warding off this complication by complete exclusion of the uterus from the peritoneum. He ligates through an abdominal incision the ovarian and uterine arteries, separates the ureters, also the bladder and rectum from the vagina, leaving the vagina intact until after the two sheets of the pelvic peritoneum, in front of and back of the uterus, have been drawn together and sutured, thus roofing over the uterus. The abdominal wound is then temporarily sutured, completely closing the cavity of the peritoneum. The uterus is then removed through the vagina, the vaginal portion being drawn out until the vagina is inverted and the whole uterus is then removed with the vagina. The only objection to this technic is the necessity to change from the Trendelenburg position to the horizontal; the only bleeding that can occur is from the vaginal artery, which is easily controlled. He reports the case which led to the development of this technic, a very large myoma complicating the carcinoma. The myoma was so large that he had to use a piece of pig bladder to patch the roof of the peritoneum over the uterus; in future he would use rubber tissue for this purpose as the bladder was fetid when expelled. But nothing of the kind is required in ordinary cases. He has treated twenty-four patients by this technic and the surprisingly smooth afebrile convalescence, without a sign of peritonitis, has confirmed the value of this method.

August 8, No. 94, pp. 985-1000

143 *Abdominal Inflammation Simulating Cancer. (Pseudo-neoplasmi inflammatori addominali simulanti tumori maligni.) R. Cassanello.

140. Thyroid Origin of Scleroderma.—Pedrazzini reports five cases of scleroderma in four of which the thyroid was small and atrophied, while in the other the thyroid was large and hard. Thyroid treatment gave good results in the two in which it was applied, commencing with small and progressive doses. None of the patients presented signs of nervous changes suggesting a trophic origin, but everything confirmed the assumption of some connection between the cutaneous affection and the thyroid gland.

141. Epidemic Resembling Typhoid.—Dell 'Oro reports a small epidemic in which the disease seemed to be typhoid from the clinical manifestations, but the bacteriologic and agglutination tests were constantly negative and the convalescence was unusually brief.

142. Influence of the Parathyroids on Fractures.—Canal's experiments showed that fractures healed very slowly in animals after removal of all or part of the parathyroids. The results indicate that the parathyroids have an important influence on the processes of ossification in healing of fractures. His findings sustain the statements of MacCallum in regard to the influence of the parathyroids on lime metabolism.

143. Abdominal Inflammation Simulating a Malignant Tumor.—Cassanello has encountered several cases of apparent cancer in the gastrointestinal tract, but operation revealed merely inflammatory infiltration, and the modifications induced by the laparotomy were followed by the complete subsidence of the tumor. By analyzing his own cases and those in the literature he finds that these inflammatory tumors spread and involve the surrounding organs to a much larger extent than a malignant tumor, so that this lack of clinical individuality, the involvement of several organs, speaks against the cancerous nature of the lesion. In one of his cases the hard woody mass included the stomach, omentum, liver and part of the abdominal wall. The lack of marked outlines and the confused objective findings distinguish these inflammatory tumors; they simulate but do not reproduce the symptomatology and objective signs and course of true neoplasms, and incision of the abdomen is generally followed by the vanishing of these apparently serious disturbances.

147 Arteriosclerosis and Heart Affections of Industrial Origin. (Arteriosclerosi e cardiopatie da lavoro.) P. Boveri.

144. Immunization to Tuberculosis.—Maragliano claims priority for immunization against tuberculosis, having immunized animals in 1895 and having now a group of patients vaccinated against tuberculosis seven years ago. He here describes the history of immunization against tuberculosis and the various technics followed and urges vaccination on a large scale of persons peculiarly exposed to tuberculous infection. The vaccine is easily made and harmless. None of those vaccinated seven years have shown signs of tuberculosis since, and he is convinced that this personal prophylaxis is the true secret of an effectual campaign against tuberculosis. It should rank with vaccination against smallpox. His technic was described in THE JOURNAL, April 2, 1904, page 933, and Dec. 8, 1906, page 1965.

155 Tonic Accommodation Reaction of Sluggish Pupil. (Om tonisk Akkomodationsreaktion af lysstive Pupiller.) H. Rönne.

149. To Keep Instruments from Rusting.—Videbech has been using for five years a mixture of crude carbolic acid and ordinary potash soap, equal parts, in a 3 per cent. solution, to prevent instruments from rusting. He has found also that one or two glass dishes filled with calcium chlorid attract any moisture in the case where instruments are kept. He does not rely on the carbolic-acid solution alone for disinfection, but boils the instruments in it and then keeps them in it.

152. Juvenile Paretic Dementia.—Neve reports the clinical and postmortem findings in two cases, discussing the etiology.

121. Nerve Connections Between the Nose and Other Organs of the Body.—Goldschmidt calls attention anew to the close connection between the nose and certain other organs, and relates a number of striking instances of complete cure—by cauterization of certain points in the nose—of pain in the stomach, genitalia, in regions innervated by the lower spinal nerves and in the head and face. His experiences confirm the assertions of Fliess in regard to the close relation between the nose and sexual organs, but he thinks that other organs are involved with equal frequency. He has not been able to find any special point in the nose connected with the various organs, but, as a rule, when relief follows application of cocain to any part of the nose, a permanent cure is obtained by cauterizing the spot with trichloracetic acid. He cites a number of instructive examples of each type. Nearly all the patients had applied merely for some nasal affection, and the discovery of the other trouble was a casual incident. In one case a woman of 30, being treated for a slight throat trouble, casually mentioned that she had had repeated gall-stone colics for seven years but had never passed any gall-stones and no treatment had been able to ward off the attacks which utterly prostrated her. He applied a cocain tampon to the outer end of the left middle turbinate during an attack and the pain was reduced in a few minutes. He cauterized the spot later and the patient was free from pain for a long time; then the colic recurred, on which he resected the part of the turbinate involved and also cocainized the outer end of both inferior turbinates and there has been no recurrence of the colic since. In another case a medical student, 28 years old, had suffered for ten years from vomiting, nausea and intense pain in the stomach after every meal, and had been under the treatment of many internists, in turn, without the slightest relief. After cocainization of the outer end of the middle turbinates the sensation of oppression in the stomach vanished. These points were then cauterized and the patient was told to eat anything he chose; notwithstanding a hearty diet there was no recurrence of pain or nausea until after the scab had dropped off, when the bone was resected and the outer end of the left inferior cauterized, since which there has been no further disturbance, the patient having been entirely cured for nearly two years. In another similar case the patient was not told that the little operation on the nose had anything to do with the stomach trouble, so that suggestion had nothing to do with the prompt and permanent cure. Cocainization of the nasal mucosa also proved effectual in curing subjective auditory and visual symptoms, and neuralgia in the face—the temporary breaking of the reflex arc evidently having a remarkably favorable influence on the disturbance. Migraine, he states, is of nasal origin in many cases, the progress of rhinology having explained it as a reflex from the nose. He warns that the nose is too important for heedless operations, while its intimate connection with so many vital organs deserves careful study.

125 [illegible] haticus. (Verhalten des [illegible] H. Shiota.
126 [illegible] berculosis. M. Laub and [illegible]

124. Movable Viscera as Sign of Predisposition to Enteroptosis.—Hausmann has been making a special study of deep palpation of the intestines and states that Stiller's congenital universal asthenia is revealed by discovery of a palpable and movable pylorus, unusually low location of the greater curvature of the stomach and of the transverse colon or a movable cecum and sigmoid flexure. When the greater curvature is only 1 or 2 cm. above the umbilicus, as the patient reclines, this indicates ptosis and is an unmistakable sign of constitutional asthenia. He is convinced of the importance of the floating tenth rib as a sign of constitutional asthenia, and advocates rejection of recruits with this finding as unfit for military service; a movable cecum and palpable pylorus are similar stigmata. In 300 persons examined the cecum was movable in 22 and all had the floating tenth rib with other signs of constitutional asthenia.

127. Prophylaxis of Postoperative and Other Forms of Ileus.—Heile makes a point of stimulating peristalsis in all cases of diffuse peritonitis, etc., by injecting from 50 to 100 c.c. of warm castor oil directly into a high loop of the small intestine before closing the abdomen. A silk draw thread closes the small hole made by the needle in injecting the castor oil. It seems to work more effectively if emulsified with a little soda and water. He has had 30 very severe cases among 250 of peritonitis in recent years, and 5 died of the 20 treated without the castor oil while only 1 died of the 10 receiving the oil, and the one fatality was in a patient practically moribund when operated on. He uses a special syringe which allows aspiration of bowel content before injection of the oil.

137 Influence of Roentgen-Ray Exposures on Prenatal Determination of Sex. (Beeinflussung des Geschlects.) M. Fraenkel.

133. Mode of Diffusion of Anesthetic in Spinal Anesthesia.—Gauss reiterates that the anesthetic spreads upward only according to the specific gravity of the solution. A solution with a high specific gravity, if the patient is seated, remains localized in the lower part of the subarachnoid space, while the cerebrospinal fluid above does not contain any of it. On the other hand, with a low specific gravity the anesthetic solution spreads rapidly throughout the fluid to the upper thoracic vertebræ which seem to be the top of the column of water, the fluid above being connected with the subarachnoid space in the brain only by capillary interstices, without any solid body of fluid. He states further that the anesthetic introduced is rapidly taken up by the spinal cord, so that the cerebrospinal fluid, even as soon as five minutes after the injection, contains scarcely any of the anesthetic, but after death the nerve substance yields up the alkaloid again so that postmortem the entire amount may be found in the cerebrospinal fluid. The results in experiments on animals can not be applied to man, as the dog has only about 6 c.c. of cerebrospinal fluid throughout the entire subarachnoid space; in the monkey the fluid is so scanty and the spinal cord fills the canal so closely that the injected fluid from lack of space is forced into the upper parts of the canal from purely mechanical reasons. If the patient remains sitting up for four or five minutes after the injection in the arachnoid space the anesthetic is taken up by the spinal cord and the individual can then recline, with the pelvis raised, without fear of spreading the anesthetic above the desired point. The high or low location of the field of operation should determine whether a solution with a low or high specific gravity is to be used. Gauss adds that he has applied spinal anesthesia in a continuous series of 1,500 cases without a mishap, the few observed in a preceding series of 300 cases being evidently due to the imperfections of the early technic.

134. **Local Anesthesia for Operations on the Female Genitalia.**—Wernitz reports 300 cases of abortion requiring curetting in which favorable results were obtained with local injection of a 1 or 2 per cent. solution of cocain representing from 0.02 to 0.04 gm. (5/16 to 10/16 grs.) of cocain. The anesthesia lasted for about 25 minutes and no mishaps were observed in any case, although general phenomena were observed—the ordinary symptoms of the action of cocain, not of intoxication. The injections can be repeated at need, he says, no cumulative effect or special after-effect having been observed in any instance.

135. **New Technic for Hysterectomy for Cancer.**—Zweifel found that peritonitis was responsible for the death in the large majority of the fatalities in the operations for uterine cancer at the Leipsic clinic, and consequently he has been devoting special attention to warding off this complication by complete exclusion of the uterus from the peritoneum. He ligates through an abdominal incision the ovarian and uterine arteries, separates the ureters, also the bladder and rectum from the vagina, leaving the vagina intact until after the two sheets of the pelvic peritoneum, in front of and back of the uterus, have been drawn together and sutured, thus roofing over the uterus. The abdominal wound is then temporarily sutured, completely closing the cavity of the peritoneum. The uterus is then removed through the vagina, the vaginal portion being drawn out until the vagina is inverted and the whole uterus is then removed with the vagina. The only objection to this technic is the necessity to change from the Trendelenburg position to the horizontal; the only bleeding that can occur is from the vaginal artery, which is easily controlled. He reports the case which led to the development of this technic, a very large myoma complicating the carcinoma. The myoma was so large that he had to use a piece of pig bladder to patch the roof of the peritoneum over the uterus; in future he would use rubber tissue for this purpose as the bladder was fetid when expelled. But nothing of the kind is required in ordinary cases. He has treated twenty-four patients by this technic and the surprisingly smooth afebrile convalescence, without a sign of peritonitis, has confirmed the value of this method.

163 [illegible] (Om Kaffe, Kaffesurrogater og kof-aber.

160. **Standardization of Drugs.**—Erlandsen reviews what has been done in this line in various countries in regard to ergot, digitalis and suprarenal preparations.

162. **The Danish-French Leprosy Expedition.**—Ehlers was the leader and was accompanied by one Danish and two French experts. Before starting, at Metchnikoff's suggestion, they spent two months at the Pasteur institute at Paris where several lepers were under treatment and volunteered as subjects for experiments, among them a medical student from Haiti with a peculiarly malignant form of leprosy. The special aim of the expedition was to determine whether insects are involved in the transmission of leprosy. Their findings all indicate that this is not the case. Even when they punctured a nodule and sucked the blood into the pipette with the mouth—a new method aiming to imitate the bite of an insect—and found numbers of bacilli in the fluid, insects biting the same person merely took up pure blood. The blood-sucking insects, he says, merely *suck blood*; they do not introduce a poison, like bees. The experiments were made on 50 lepers in the Danish West Indies, and the Wassermann test gave constantly positive findings in all patients with nodular leprosy, while the reaction was vague or negative in the anesthetic form and in the stationary and cured cases. The expedition regards this test as destined to prove as important in leprosy as it has been found in syphilis. *Turpentine fixation* abscesses gave negative results, and no signs of leprosy were found in 160 rats examined. A casual finding was the discovery of *Filiaria sanguinis hominis* in the stomachs of body-lice. The chief expenses of the expedition were borne by the Danish engineer, Davidsen, at Paris; the French government this [illegible] the expenses of one member; the transportation com-tional ast[illegible]arried them all free of charge. floating tent[illegible]way home Ehlers stopped at Porto Rico and states advocates rejec[illegible]s that leprosy there is much more common than military service; [illegible]nized. He mentions in conclusion that he was similar stigmata. [illegible]shington, on his arrival in New York, to tes-[illegible]xpert in the case of a man (Early) who was suing the authorities for damages for unwarranted incarceration, as compulsory isolation had been imposed on the assumption that he was a leper. After careful examination Ehlers thought that the man really was afflicted with leprosy, contracted in the Philippines. [This case has been mentioned in The Journal, and an account of it appears in the September *Munsey*. The patient is now under observation at the New York Skin and Cancer Hospital, but not under restraint.—Ed.]

THE RELATION BETWEEN THE SCIENCE AND THE ART OF INFANT FEEDING *

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

During the past few years there has been much discussion in reference to scientific infant feeding. On closely examining the points discussed, however, it will be found that little attention has really been paid to the science of infant feeding, as almost all the efforts have rather been directed to the art of infant feeding. The science of infant feeding consists in knowing why certain things should be done, or not done, and the effects of different procedures. The art of infant feeding comprises the methods employed in preparing food and administering it. Most of the articles concerning infant feeding have related to methods of making foods acceptable to infants, and many diverse methods have been proposed. As infants have been found who have thriven, to a certain extent, on all of the different methods that have been advocated, it is evident that there has been something in common possessed by all of them.

The reason that every method of infant feeding can be shown to have been occasionally successful is that all of the foods contained more or less proteins, mineral matter, fats and carbohydrates, without which no infant can live or grow. Various infants will thrive on some foods better than on others, owing to the fact that the food elements are present in more suitable quantities and forms. The form of a food element has an important effect on its usefulness, and a large part of successful, practical feeding consists in changing or adapting the form of the food elements to suit different infants, for they are not alike in their capacity for digesting and assimilating even the same forms of food elements.

It is self-evident that the infant belongs to the animal kingdom and is accordingly subject to the general laws of animal nutrition.

It is also evident that the infant is still in the last stages of embryonic development while normally at the breast, and that its digestive organs are not adapted for ordinary food. All young mammals are in this condition for some time after birth and it is found that the food supplied by the mother has the property of changing its physical form when it comes in contact with the gastric secretions of the young. The food assumes a more or less solid form in the stomach, and the character of this solid differs as the stomachs of the young animals differ, rather than according to the composition of the food. The composition of the food supplied by the mothers of various species of young animals varies according to the rate of growth of the young, the milk supplied to rapidly growing young animals containing *more protein than that furnished to those whose growth* is less rapid.

In reference to the infant's nutrition, we have always to deal with milk in some form, as biology shows that this is always the primary and elemental food mixture, containing in easily assimilable form all the food principles. While the different manipulations required to make various milks, or other forms of food, acceptable to the infant's stomach constitute the art of infant feeding, before any of these details can be accepted as scientific and thus of permanent utility, it must be decided how far they are in accordance with biologic laws. Biology must thus finally decide both the possibilities and limitations of every method that is advanced. This will call for a knowledge of the structure and functions of the various digestive tracts in connection with the peculiar characteristics of the milk early furnished to each species. This study will show not only how far different milks are interchangeable, but also throw light on the various manipulations that aim to make them so.

A chemical analysis of milk will show the ingredients of this fluid, and, to a certain extent, their potential food values from their quantitative amount. There is something beyond this, however, that chemistry can not explain. While the fats and carbohydrates in their composition and reaction to the digestive secretions are a good deal alike in different milks, the proteins are essentially different. Chemistry alone can not explain this phenomenon. We must study the reaction of the protein to the digestive secretions, and then examine such reactions in relation to the growth and development of the digestive tract—in other words, investigate the question biologically before we can understand the problem. A certain portion of the protein of all milks coagulates on coming in contact with rennin or rennin and acid, but the manner and extent of this coagulation stands in a direct relation to the proper evolution of the digestive tract of the animal.

While there are many grades of coagulability in the milks of different animals, for practical purposes, we may distinguish three of these grades and consider their significance. The protein may coagulate in a solid, gelatinous or flocculent manner. In the ruminant, herbivorous animals, such as the cow, sheep or goat, the protein coagulates in solid, tough masses that can not readily leave the stomach. In these animals, digestion is always largely gastric and the stomach forms 70 per cent. of the digestive tract. Later, this stomach will be called on largely to digest tough, stringy masses of hay and straw and the previous exercise on the tough curds of the milk develops it for this future work. In the non-ruminant herbivora, such as the mare and ass, the protein coagulates in gelatinous masses that can easily leave the stomach. The reason for passing the curds quickly along is, that in this class of animals digestion is largely intestinal, and the intestines form about 90 per cent. of the digestive tract. Later, grain and grasses must be largely digested in the intestinal portion of the tube, and hence the curd is here also especially adapted to develop the intestinal tract for its future work. In human milk, the curd is thrown down in flocculent masses—a form intermediate between the solid and gelatinous types of curd previously noted. While digestion begins in the stomach it is largely carried on and completed in the intestine, and the stomach forms about 20 per cent. of the digestive tract. The curd is thus adapted to start the development and motility of the stomach and finishes by instituting these functions in the bowel which is destined to play a predominant part in digestion. Here again the curd, so far as the form is concerned, furnishes an analogue and precursor of the future food of the infant. The curd forms small, flocculent masses, and the future food must be separated later into small masses by chewing before digestion can take place to the best advantage.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

We have thus seen that the milk of herbivorous animals whose digestion is principally gastric forms solid curds which can not easily leave the stomach; that the milk of herbivorous animals whose digestion is principally intestinal forms gelatinous curds which easily leave the stomach and pass into the intestines; and that women's milk, which is intended for a digestive system in which gastric digestion is more than that of the horse or ass, but not so great as the cow or goat, curds in flakes that stand between the other two types of curds.

Biologic science thus shows us that, while a certain amount of protein is present in the milk of all animals, and is necessary for tissue building and growth, this protein must not only be coagulable, but must curd in a certain specific way in each species of animal. The protein is thus the least readily interchangeable of the ingredients of the milks of different species. In this way, science teaches that the protein must not be thrown into a soluble form or so altered as not to react normally to the digestive secretions if we would have healthy growth. We must always remember that the protein has a developmental as well as nutritive function to perform. While immediate nutrition is of great importance to the growing infant, we must not, by putting all food in a soluble form for quick absorption, neglect to give proper work for the secretions and musculature of the digestive tract. It is only by the latter method that the natural food for the adult can later be digested by a normally developed tract. The science of infant feeding will thus influence the art by showing what should and what should not be done in the various manipulations that may be advised. Briefly, all the food principles must be present and in about the same proportion as in the natural food of the infant. Chemistry will tell us this from an average of many examinations, but can not say the final word. It can tell us that protein exists in certain amount, but the form and adaptation of the protein for the infant's digestive tract can only be determined by biologic methods.

A few simple illustrations may show the practical application of these biologic standards. From chemical analyses we know approximately the quantity of protein an infant needs to produce growth. If chemistry alone is the standard, any form of protein should be satisfactory. It would be possible to give sufficient protein in the form of whey, but this protein (lactalbumin) is in solution and remains fluid in the digestive tract. The same would be true of complete peptonization. However desirable for temporary use, for routine employment these forms of milk are contraindicated by the biologic principle that in all young animals a portion of the protein of the milk is thrown by the young stomach into a more or less solid form, which evidently has for its purpose the development of the motility of the digestive tract.

As another example, if there is a persistent appearance of curds in the stools, it may indicate an intestine too weak in digestive power to take care of the normal curd. Here the use of a substance like citrate of sodium may be scientifically indicated from its action in altering the character of the curd to make it suit the weakened condition of the bowel. As a routine measure for normal infants, however, this should be looked on as an unscientific procedure.

Again, it is well understood that gastric digestion in the adult depends essentially on the action of pepsin and hydrochloric acid on proteins, and in infancy there is little acid secreted. As the stomach develops, more pepsin and acid are secreted. Is it not, then, contrary to biochemical science to check the beginning action of the gastric secretion by loading the food with bicarbonate of sodium, or other strong ant-acids, as a routine measure? Biology teaches that organs improve in capacity by a normal increasing use. What chance has the stomach to develop its function if the food constantly contains ingredients that will more than neutralize the acid it secretes and thus check one of its functions? On the contrary, if there is an acid intoxication, or an abnormally acid secretion, then it will, indeed, be scientific to correct such abnormal conditions by giving ant-acids. These illustrations show that when the science of infant feeding is understood the methods to be used under different conditions will be self-evident, which could never be the case so long as chemical data alone are assumed to be the exclusive basis of scientific infant feeding.

The scientific principles involved in infant feeding are few and simple. The methods of applying them are many and may be as simple or as complex as one desires to make them. The point ever to be kept in mind is: What is the effect of a proposed method and does it apply correct scientific principles? Many of the methods that have been proposed are unscientific when employed as routine measures, although they may be scientific under certain conditions; and methods that may be scientific as routine measures may be unscientific when applied to abnormal conditions.

Various methods of preparing food have been well worked out and simplified, but they will be of little value to the physician unless he knows why, and how, and when to use them. In this way only can scientific methods prevail. Infant feeding can only become scientific by being placed in line with the methods of science in general.

Early Use of Chloroform in Eclampsia.—J. R. Fothergill, in the *Journal of Obstetrics and Gynecology of the British Empire*, reports a case of eclampsia, occurring in 1849, in which his father, John Fothergill, M.R.C.S., used chloroform to control the convulsions during delivery. He states that this is probably one of the earliest recorded cases in which chloroform was used for this purpose.

INVESTIGATION OF BLOOD FOR TUBERCLE BACILLI

CONTAMINATION OF DISTILLED WATER WITH ACID-FAST ORGANISMS A SOURCE OF ERROR

WALTER V. BREM, M.D.
Chief of the Medical Clinic, Colon Hospital
CRISTOBAL, CANAL ZONE

In view of the recent publications by Rosenberger[1] of the remarkable results of his investigations of the blood for tubercle bacilli, it seems worth while to publish my experiences in a similar investigation conducted in November, 1908, without knowledge of this author's work. The report is intended to repeat a warning by calling attention again to the dangers of contamination with other acid-fast organisms.

In his text-book, "Clinical Pathology of the Blood," Ewing reviews briefly the work done previous to 1891, in which various investigators found tubercle bacilli in the blood. He then says: "Grave doubt was, however, thrown on all previous work in this field by the negative results obtained by Guttman and by Kossel, who called attention to the danger of contamination in such specimens. This method of diagnosis has not been followed up in later years, although Kronig, in 1894, recommended the staining of centrifugalized laked blood in doubtful cases of miliary tuberculosis." Ewing further cites Kuhnau, who obtained only one positive result from twelve inoculations with the blood from severe febrile cases of tuberculosis.

TECHNIC

It should be recalled at once that ordinary methods of heat sterilization have no effect on the staining properties of tubercle bacilli and of the other members of the acid-resisting group of bacilli. Exposure for a few seconds to pure nitric acid, however, and also to the direct flame destroys their staining properties. In this work, therefore, the slides and cover-glasses used were exposed to the flame, and other glassware was treated with pure nitric acid and rinsed with alcohol and ether. A few drops to 10 c.c. of blood were drawn either from a vein or from the finger-tip, the skin being cleaned with soap and water, alcohol and ether. For laking the blood I used very dilute acetic acid or 0.2 per cent. ammonium oxalate in distilled water, which was furnished daily by the Canal Commission for drinking purposes. This laked blood was then centrifugalized and smears made from the sediment, a very pretty field of thickly spread leucocytes being obtained. Each cover-glass smear was traversed ten times with the 1/12 lens, as an arbitrary standard of search. Nitric acid, 25 per cent., followed by 95 per cent. alcohol, decolorized the preparations, and a counter-stain of methylene blue was used. The distilled water and all solutions used were repeatedly centrifugalized, and smears made from the sediment were examined for acid-alcohol-resisting bacilli. At first results were constantly negative. An earnest attempt was made to exclude every possibility of contamination.

BLOOD EXAMINATIONS AND ANIMAL INOCULATIONS

On Nov. 1, 1908, a patient was admitted with high fever, meningeal signs, convulsions, and a moderate leucocytosis. Blood culture (10 c.c. in Conradi's medium) gave no growth after twenty-four- and forty-eight-hour transplants on agar. Lumbar puncture, November 2, showed an increased quantity of cerebrospinal fluid under a pressure of 212 mm. The fluid was very faintly turbid, contained a considerable quantity of proteid, and a slight increase of leucocytes, the large mononuclears predominating. Cultures from the spinal fluid were negative. A portion of the fluid was diluted with distilled water, centrifugalized and examined. Acid-alcohol-resisting bacilli were found. The patient died November 3, and the autopsy showed edema of the cerebral meninges; bronchopneumonia; a small tuberculous cavity, 1 cm. in diameter, in the apex of the right lower lobe; a calcified and pigmented tubercle, 1.5 by 1 cm. in size, in the pleura of the right lower lobe; one calcified peribronchial lymph-node on the right side. Cultures on agar-slant from the spleen were negative.

Having found tubercle-like bacilli in the spinal fluid, the idea suggested itself that this case might be one of "typhobacillose" described by Landouzy.[2] I took, therefore, a portion of the bile, in which had been placed 10 c.c. of blood, diluted with distilled water, and centrifugalized. In the smear 58 acid-alcohol-resisting bacilli were found. A diagnosis of acute tuberculous septicemia was made. Fifteen days later, after most of the work had been done, it occurred to me that it would be interesting to make another transplant from the bile-blood culture, which had been fortunately saved. To my surprise, a fairly good growth on agar of a small diplococcus was obtained. On blood agar, after several transplants, this diplococcus developed a well-defined, distinctly staining capsule, and proved to be a pneumococcus. Pneumococcus septicemia, without pulmonary consolidation, is not an infrequent occurrence in Panama, and in several cases I have been able to isolate the organism from the blood before a meningitis developed and when there were no signs other than high fever, leucocytosis, arthritis or epididymitis. Eventually, therefore, the diagnosis in this case was corrected to pneumococcus septicemia.

The first findings, however, led me to investigate the blood of other patients, and in cases of pulmonary tuberculosis the results were uniformly positive. Altogether twenty-six positive examinations were made, including cases of pulmonary tuberculosis, cervical and inguinal adenitis, pleurisy with effusion, miliary tuberculosis, intestinal hemorrhage of obscure origin, abdominal pain and diarrhea, dysentery of obscure origin, arthritis of hip-joint, and other obscure fevers. In none of these cases could a diagnosis of tuberculosis be excluded clinically. There were negative results in one case of pneumonia, one of cervical adenitis which later subsided with antisyphilitic treatment, one case of pregnancy, and one of obscure continued fever. During this time there was only one autopsy on a non-tuberculous body. Examination of a mixture of cerebrospinal fluid and blood from this case showed two atypical and indefinitely staining, but suspicious bodies.

These remarkable results were rendered more credible by certain coincidences which seemed to be at the time convincing evidence of their validity. Two patients were admitted early in the course of an acute continued fever, the temperature ranging from 102 to 103. Blood was taken at the same time for cultures in ox-bile and for examination for tubercle bacilli. The examination for tubercle bacilli was made at once with positive findings in each case. Although both resembled typhoid ruminant herbivora, such as the mare and ass, the protein coagulates in gelatinous masses that can easily leave the stomach. The reason for passing the curds quickly along is, that in this class of animals digestion is largely intestinal, and the intestines form about 90 per cent. of the digestive tract. Later, grain and grasses must be largely digested in the intestinal portion of the tube, and hence the curd is here also especially adapted to develop the intestinal tract for its future work. In human milk, the curd is thrown down in flocculent masses—a form intermediate between the solid and gelatinous types of curd previously noted. While digestion begins in the stomach it is largely carried on and completed in the intestine, and the stomach forms about 20 per cent. of the digestive tract. The curd is thus adapted to start the development and motility of the stomach and finishes by instituting these functions in the bowel which is destined to play a predominant part in digestion. Here again the curd, so far as the form is concerned, furnishes an analogue and precursor of the future food of the infant. The curd forms small, flocculent masses, and the future food must be separated later into small masses by chewing before digestion can take place to the best advantage.

Two patients were admitted early in the course of an acute continued fever, the temperature ranging from 102 to 103. Blood was taken at the same time for cultures in ox-bile and for examination for tubercle bacilli. The examination for tubercle bacilli was made at once with positive findings in each case. Although both resembled typhoid fever, I predicted that the cultures would be negative for the typhoid-colon group. They proved to be so.

[2] Internat. Cong. on Tuberculosis, Washington, 1908, Section ii, No. 2.

A typhoid fever patient, who had given a positive blood-culture, developed meningeal signs. On lumbar puncture 30 c.c. of clear fluid under a pressure of 200 to 225 mm. was obtained. It contained a small quantity of proteid and two leucocytes per c.mm. A culture made in ox-bile was negative for typhoid bacilli. Before this fluid was examined for tubercle bacilli the patient died and the autopsy showed typhoid lesions, but no tuberculous lesions of the cerebral meninges. Immediately afterward I examined the spinal fluid by precipitating the proteid with alcohol, dissolving in sodium carbonate 0.6 per cent. in distilled water, centrifugalizing and making smears from the sediment. Seventeen tubercle-like bacilli in one smear were found. Dr. Williamson, the pathologist, at my request, then removed the cord. Caseous areas were found scattered in the spinal meninges. Tubercle-like bacilli were found in the blood preparations, also, from this case.

In another instance, for a control, an apparently healthy patient, who had been admitted for malarial fever and who had had no fever for several days, was selected. In his blood acid-alcohol-resisting bacilli were found. I then made a more careful examination of the patient and discovered a pleural effusion reaching about 4 cm. above the normal border of the base of the left lung. The diagnosis of effusion was confirmed by thoracentesis.

Another patient had a high continued fever, the temperature remaining at 104 to 105 F. for two weeks. Two blood cultures in ox-bile were negative; leucopenia was marked with an almost complete absence of polymorphonuclear leucocytes which fell to 5 per cent. There was a profuse hemorrhage into the conjunctivæ with purpura of the lids; other purpuric areas developed on the trunk, and there appeared peculiar bullous skin lesions, very superficial on a hemorrhagic base. Extensive noma of the lower lip developed, a few scattered râles were present in both lungs, the spleen was enormous. Tubercle-like bacilli were found in the blood, stools, urine and scrapings from the base of one of the skin lesions. The stool was boiled in 0.6 per cent. sodium carbonate in distilled water and centrifugalized; the urine was diluted with distilled water, sedimented, and the lower portion centrifugalized; and subsequently I learned that the ward physician who examined the skin lesion had teased the scraping in distilled water. A lesion examined later without using water was negative. A diagnosis of miliary tuberculosis was made. Later, and after I had discovered the source of contamination, the patient's fever terminated by crisis and recovery was good. I was never able to arrive at a satisfactory diagnosis.

These [illegible] bacilli were likewise readily found [illegible] and in stools and urines examined by the method indicated above. The morphology of the bacilli was typical of tubercle bacilli. There were long beaded forms and shorter solidly-staining ones; they were frequently scattered, but usually in clumps of two, ten, thirty, and sometimes one hundred or more. The number of bacilli in one cover-glass preparation varied from two to several hundred.

During all this time, sources of error in technic or sources of contamination were diligently sought, for the ease with which positive results were obtained rendered it almost incredible that such a bacillemia had not been demonstrated before. The water, sodium carbonate, sodium hydrate, ammonium oxalate, acetic acid, and alcohol were repeatedly centrifugalized separately and smears from the sediment examined with negative result. The carbol-fuchsin solution and methylene blue were likewise examined and nothing found. More time was consumed in searching for error than in the examination of blood.

On November 11 the heart's blood of five guinea-pigs was drawn for examination. On November 12 four of these pigs were inoculated intraperitoneally with the sediment from three to nine drops of blood taken from two positive cases of pulmonary tuberculosis and two cases of suspected tuberculosis. The fifth pig had been inoculated subcutaneously on October 11 with sputum from a case of [illegible] tuberculosis. Immediately after [illegible]ds drawn the day before from the heart were examined and tubercle-like bacilli found in all five instances. One of the pigs inoculated from a suspected tuberculous case was killed at once, and the autopsy showed no tuberculous lesions. But again in blood taken from its heart at autopsy similar bacilli were found. The other four pigs all remained healthy for more than four months. On March 19, 1909, two more of them were killed and examined with negative results. One of these had been inoculated with blood from a patient with pulmonary tuberculosis, the other with sputum from the suspected case. The remaining two, being apparently healthy, were returned to the pen.

The result of the examination of these guinea-pigs weakened my faith in the validity of the observations and stimulated my desire to find a source of contamination. On November 13 scrapings were made from the hair and skin of a guinea-pig and from the skin of my hands. These scrapings were placed separately in dilute acetic acid made with distilled water, in order to reproduce the technic of blood examinations, and the suspension was centrifugalized and sediment examined. Tubercle-like bacilli were found in both instances.

THE SOURCE OF ERROR

On November 14 the real source of error was discovered by the simple device (which should have been used before) of fixing to the slide with egg albumin the sediment from distilled water in the laboratory jar. In traversing the smear one time about 600 acid-alcohol-resisting bacilli were found. Smears made with egg albumin alone were negative. Other laboratory solutions made up with distilled water were then examined in the same way, and sodium carbonate, sodium hydrate, ammonium oxalate, etc., were all found to contain similar bacilli. Freshly delivered distilled water (250 c.c.) was sedimented and examined. I estimated that in one cover-glass preparation there were about 30,000 of these organisms. In the tap-water an occasional acid-alcohol-resisting bacillus could be found, about one in each loopful of sediment. The sediment from 250 c.c. of distilled water and from 1,000 c.c. of tap-water was used to inoculate guinea-pigs. They both remained healthy, and at autopsy March 19, 1909, showed no tuberculous lesions.

I now had distilled water made in the laboratory. The receiving flask was treated with pure nitric acid, and, after the first portion of the distillate had passed over, the flask was rinsed with the second portion, and the third portion was saved. The flask was plugged with cotton, which was not sterilized. Examination of the bottom portion of this water (fixing with egg albumin) was negative for tubercle-like organisms.

To a portion of spinal fluid that had shown acid-fast bacilli on previous examination with Canal Commission distilled water, alcohol was added, and the precipitated proteid centrifugalized and examined with negative result. A portion of a pleural effusion was placed in 0.2 per cent. solution of ammonium oxalate (prepared with the laboratory distilled water), centrifugalized and examined with negative results. A bile-blood culture from an obscure case of remittent continued fever, in which tubercle-like bacilli had been found previously, was centrifugalized and examined. Five suspicious bodies were found, but they were atypical and indefinite.

It was my intention to review the work with water and solutions assuredly bacteria-free, but circumstances at that time and since have prevented. When Rosenberger's first article appeared three months later, however, I selected a positive case of pulmonary tuberculosis and examined the blood by his method, using my old laboratory distilled water in making up the citrate solution and in laking the blood on the slide. I had no difficulty in demonstrating acid-alcohol-resisting bacilli.

I then made three thick blood smears directly on glass slides, laked the blood with the laboratory distilled water and examined them. The first two smears were negative after a thirty-minute examination of each, but in the third I found fifty-seven tubercle-like bacilli in fifty-five minutes. This seemed to be very conclusive, for absolutely the only source of contamination had to be the distilled water which was allowed to dry on the smear after laking the blood. But, my confidence in distilled water having been shaken, I examined with egg albumin the small sediment that had formed and found considerable numbers of acid-alcohol-resisting bacilli.

The identification and description of this organism and the method of contamination remain for further investigation. It is probable that they belong to the grass bacilli. Guinea-pigs were kept in the laboratory where my water was distilled and kept, and the Canal Commission water was delivered in tanks drawn by horses. In both instances it is not very difficult to see how contamination might have occurred.

It seems probable, also, that contamination of distilled water with acid-fast organisms does occur frequently in all laboratories where animals are kept. Recently I have had an opportunity to examine the distilled water of a laboratory in the State of New York. Animals are kept in the basement of this laboratory just beneath and communicating with the room where water is distilled and kept. The still is a Jewell Automatic, and the glass reservoir for distilled water is constantly connected with the still by means of a rubber tube passed through a cotton plug. Acid-alcohol-resisting bacilli were demonstrated in the small quantity of sediment in the reservoir. In a second laboratory, which is on the third floor of a building, in the basement of which animals are kept, no tubercle-like bacilli were found in the distilled water, but there were present acid-semifast (Piffard) spore-like bodies which might have caused some uncertainty if present in suspected specimens.

Rosenberger makes the following statement:

> In the investigations I used sodium citrate solutions made at five different institutions. Some of the spreads were made in one laboratory and laked and stained in another. . . . The solutions of sodium citrate and ammonium oxalate were sterilized by the autoclave or steam sterilizer. . . . Spreads made from the *sediment* [italics mine.—W. V. B.], which occasionally took place in the citrate solution failed to show any so-called citrate bacilli.

Rosenberger fails to state explicitly whether or not a thorough search for acid-fast bacilli in the citrate and oxalate solutions and in the distilled water used in laking the blood was made by fixing the sediment with albuminous material. This procedure in technic is the crux of the whole matter. One result of his animal experiments, 30 guinea-pigs showing acid-fast bacilli in the blood suspensions while having no tuberculous lesions, is strong evidence in favor of contamination rather than of the presence of tubercle bacilli in the circulating blood. Had he examined the blood of these guinea-pigs *before* inoculation, as was fortunately done in my series, his results would probably have been the same. Evidence in favor of Rosenberg's view, however, is furnished by his negative autopsies on seven bodies whose blood suspensions during life had been negative for acid-fast bacilli. But it is only necessary to refer to the almost convincing coincidences of my own work to indicate that "experience is fallacious and judgment difficult."

SUMMARY

1. In examining blood, urine, stools, sputum and exudates for tubercle bacilli, the greatest care should be used to exclude contamination of water and all solutions used with members of the acid-resisting group of bacilli (whether dead or alive).

2. In this investigation, coincidences occurred which were all but convincing of the presence of tubercle bacilli in the blood in every case of tuberculosis.

3. Animal experimentation was negative, but the quantity of blood used for inoculation was too small for the results to be of great value.

4. Acid-alcohol-resisting organisms were found eventually in fresh distilled water furnished by the Isthmian Canal Commission, in tap water, in old distilled water made with care in the pathologic laboratory, and in all solutions made up with the Canal Commission water. These bacilli were either dead or non-pathogenic to guinea-pigs.

5. There is as yet no conclusive proof of the frequent continued presence of tubercle bacilli in the circulating blood.

I wish to express my thanks to Col. W. C. Gorgas for permission to publish this report, and to Dr. Wiliamson, pathologist, and Dr. Glines, in charge of the clinical laboratory, for their interest and assistance in the work.

MEDICAL VERSUS LEGAL RESPONSIBILITY *

PHILADELPHIA

Among the various problems of human activities there is none more important than the relation of mental state to responsibility. The idea of human liberty and responsibility forms the basis of the penal system. This principle has been recognized by law as indispensable in order to assure the working of social discipline. The doctrine of liberty is old and in its crude form is accepted now, but modern science, based on accurate clinical and experimental methods, has helped to modify to a great extent the fundamental features of the old conception of liberty and responsibility. Mental medicine, through its more elaborate classifications and its continuously widening field of investigations, has revealed new pathologic manifestations and types which previously had not been suspected. Normal and pathologic psychology in its turn has availed itself of these discoveries and assisted in throwing light on the obscure problems of personality, memory, volition and reason. The conclusions of modern science lead to a broader and more humane consideration of human responsibility. The old traditions and the material interest which are threatened are not the only elements to be considered. The individual himself, his most intimate and most profound beliefs, the principles of his life in all its manifestations, in the domain of his individual consciousness as well as in their application to social discipline—all these questions are taken into consideration by modern science in its effort to arrive at a proper appreciation of mental responsibility.

---

* Read in the Section on Nervous and Mental Diseases of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Unfortunately the new investigations do not always bear the fruit which could and should be expected. One of the principal reasons is the fact that the studies of the subject are ignored by those who create the laws and those who administer justice. They view exclusively the social side of the law and are not at all interested in psychologic and medical studies which present a different concept of criminality and of the criminal himself. It is true that penal legislation and legal medicine are distinct and separate sciences, but positive criminology must rely on both branches of human knowledge. An intimate unity of these two sciences is an indispensable and an essential condition of progress. Mathematics is a rational science, physics is an experimental science; a union of the two helped to reveal the essential phenomena of matter. Chemistry and medicine are also distinct sciences, but Pasteur's work built the bridge between the two. Psychology finds its elements in mental pathology and physiology. Modern philosophy is bound to look for assistance in medical sciences.

Criminology has for its object the formation of positive laws concerning crimes and the discovery of remedies for them. With this object in view it searches the truth wherever it can be found and takes from medical and legal sciences data which it needs to form a scientific foundation. By the union of the two sciences the old and too narrow boundaries of human conception of liberty and mental responsibility will be broken and progress will be assured.

An attempt in this direction is presented in the present essay, which is based on a personal experience in the courts of the State of Pennsylvania.

In a number of instances of civil and criminal cases in which the question of responsibility was involved the main issue consisted of the test of "right and wrong." Every other element has been invariably eliminated by the skilful attorneys and even by some judges. It seemed in many cases that the criminals' legal knowledge of right and wrong was all that was necessary for determining the question of whether they were mentally responsible or not. The expert has not been permitted to enter into any explanation and to refer to any facts of the criminal's life, character, demeanor or to facts of marked hereditary nature indicating abnormality of mental processes or insanity, feeble-mindedness, imbecility—all showing complete or limited responsibility. Mentally abnormal individuals, as we shall see later, may know the distinction between lawful and unlawful acts and still be not mentally responsible.

The first test of wrong and right was proposed in 1843 by fifteen judges in England. It appears in the phrases "unable to distinguish right from wrong," or to discern "that he was doing a wrong act," or was "ignorant that he was committing an offence against the laws of God and nation." In 1846 Chief Justice Gibson, of Pennsylvania, said:[1]

> A man may be mad on all subjects; and then, though he may have glimmerings of reason, he is not a responsible agent. This is general insanity; but if it be not so great in its extent or degree as to blind him to the nature and consequences of his moral duty, it is no defence to an accusation of crime. It must be so great as entirely to destroy his perception of right and wrong, and it is not until that perception is thus destroyed that he ceases to be responsible. It must amount to delusion or hallucination controlling his will, and making the commission of the act in his apprehension a duty of overruling necessity.

Speaking further on partial insanity, the judge remarks:

> Insanity may be confined only to one particular subject, and then the individual continues to be a legitimate subject of punishment, although he may have been laboring under an obliquity of vision; a man whose mind squints, unless impelled to crime by this very mental obliquity is as much amenable to punishment as one whose eye squints.

Afterward in 1858 the judge said:[2]

> So far as the act is concerned, insanity must be so great in extent and degree as to blind him to the natural consequences of his moral duty and must have utterly destroyed his perception of right and wrong.

The legal conception of insanity as defined in these few examples had such a strong hold that it could not be shaken. It continued to form the basis of decisions and rulings in subsequent cases.

In spite of advancement of scientific research in the field of mental science and psychology, the results are totally or greatly ignored by some jurists. In many instances they continue to follow the old traditional path, no matter how unscientific, irrational and inhumane the test of right and wrong may be.

In discussing the various forms of mental disease we shall see that a person in committing a crime may realize the enormity and the lawlessness of the act and still be irresponsible for the act. The so-called moral insanity presents the most striking example of impracticability of application of the generally accepted test. Here the abnormal moral conceptions, the extraordinary propensities, eccentricities, the abnormal conceptions of obligations, etc., may be present a long time together with the proper conception of wrong in a criminal act. Shall such an individual be considered entirely responsible?

In sane life the knowledge of right and wrong is not the only factor that affects the free choice of our actions. We have to count also with impulses, with powerful motives. The power of restraint is in a certain relation with ideas and feelings which are opposed to the impulses. Will-power may suppress the latter. Will-power depends on the power of deliberation and self-control. The latter two factors differ immensely in various individuals. In normal life consequently an overwhelming pressure of external circumstances may sometimes and in some individuals remove to the background and even check completely the power of restraint or of self-control, although the distinction between right and wrong is totally preserved.

The pathologic states of mentality are characterized precisely by a more or less marked diminution or even complete abolition of the power of deliberation, of will.

---

[1] Commonwealth vs. Mosler, 4 Barr, 264, 1846.

[2] Commonwealth vs. Ferth, 3 Phila. 105, 1858, per Ludlow, J.

of self-control, and yet the ability of understanding that an act is morally wrong or forbidden by law may be present in its integrity.

Let us, therefore, consider in detail the various forms of mental abnormality in connection with the principle of right and wrong.

In melancholia, homicide occasionally occurs. The individual kills because he does not wish the victim to suffer through his sins. The delusion is usually intensified by hallucinations and the latter hasten the act. Here an insane motive prompts the action and the morbid condition has affected the mind generally so that the impulse of action is derived from the state of feeling and thought. The distinction between right and wrong is impossible.

In mania all the functions are exalted and there is more or less marked diminution of controlling power, so that even slight stimuli may lead to intense actions. In ordinary cases the intellect is not affected and the individual committing an unlawful act may know perfectly well the significance of the act and still, because of the decrease or complete disappearance of inhibition power, which forms the essential characteristic feature of the disease, the impulse is overwhelming. It is, however, true that in pronounced cases or in chronic cases there is an intellectual weakness and a confusional state so that the maniacal patient is then incapable of understanding the nature of his acts.

In no form of mental disorder can the legal test of right or wrong lead to more errors than in a certain class of paranoia. In the hallucinatory variety of this psychosis the impulse to poison, to kill, to massacre, to persecute is prompted by the hallucinatory images and the power of discriminating between a lawful and unlawful act is distinctly abolished. In another variety of paranoia, the individual is to all appearances a reasonable being, capable of comprehending an ordinary conversation, capable of discussing various subjects, and still on one particular subject his judgment is paradoxical and abnormal. He may then fail to exhibit in a long conversation evident signs of mental derangement until the subject of his main or only delusion is touched on. This is the so-called "partial insanity." Jurists and laymen then say that that individual's insanity is confined to a particular subject, the man being sane in every other respect. Sometimes they say that the man's criminal act is only the expression of depravity or of passion which in their eyes does not appear to differ materially from those of sane men and consequently the criminal impulse is simply an incident in the life of a sane man who is expected to overcome it. Such an individual, in spite of his apparent sane demeanor and attitude not infrequently labors under a special and fixed delusion which he conceals quite skilfully. He silently contemplates revenge and in the most careful and deliberate manner he plans its execution. The criminal knows perfectly well that he is committing an offence against the law and that he may be punished, but his act is prompted by an irresistible impulse which is the direct result of his delusive ideas. In this class of cases one must consider the true factors affecting the criminal act, viz.: the delusion, the defective power of inhibition and the abnormal feeling. These are the only elements that affect the power of free action. They alone must be taken into account in our attempt to appreciate a paranoiac's action. The legal view is totally inadequate and narrow, as alongside of those morbid elements the realization of an unlawfulness of an act may be well preserved.

In general paralysis of the insane the question of responsibility may come up during any of the periods of the disease. When the dementia is pronounced, there can be no doubt as to the patient's incapacity of distinguishing wrong from right. But before mental failure becomes accentuated, the individual may present only peculiarities of conduct, tendencies to deception, fraud or theft, extravagant mode of living, suspicious relations to his surroundings and in addition to this some physical signs also—all showing clearly the development of paresis. While committing an unlawful or criminal act the patient may be fully aware of the illegality of such act and of the consequences he will have to suffer for such an act; nevertheless the man is insane in the true sense of the word and the criminal act itself, as well as the above abnormalities of disposition, character, conduct, is an early sign of the disease. If the test of right and wrong is strictly applied to such cases, the man must inevitably be punished and when the crime is assault and murder he will be hung or electrocuted. Such a procedure is unquestionably a miscarriage of justice and essentially inhuman. A paretic at any of the phases of his disease is insane: his power of control, his feeling, his deliberation are fundamentally defective, abnormal and consequently his acts are the result of sudden morbid impulses. These are the immediate causes of his irresponsibility, but not the legal principle of right and wrong. Illegal acts are sometimes the first manifestations of the disease and the peculiar features with which they are sometimes surrounded lead us to the right road for a diagnosis.

Senility is not necessarily a cause of irresponsibility. Many individuals preserve the integrity of mental faculties until a very old age. When the senile involution has progressed so far as to abolish completely the faculties, all responsibility disappears. But the involution may be slow, irregular and at the same time progressive, and in such cases there may be a long phase during which the moral conceptions, obligations, the sense of propriety, affection may gradually undergo radical changes so as to lead to most unexpected acts. A senile dement, no matter how slight his dementia may be, is apt to commit the most extraordinary acts. In making a will, for example, he may be guided by petty motives which are easily aroused; anger, desire for revenge, jealousy can be stimulated with the greatest facility, and a will signed by a senile dement may express the most extraordinary, most unjust, most inhumane wishes. As he is easily influenced, he may change his will at each change of his humor. In spite of this variability of actions, he may be fully aware that he is doing a wrong act. He may fully realize the injustice done to persons whom he deprives of the worldly goods and he will, therefore, be legally responsible. The test required by law is positive here, but is it just? A senile dement is in a pathologic state; he is insane in the most proper sense of the word. Scientifically he can not be considered responsible, and consequently by relying exclusively on the classical legal test, injustice is easily done.

Let us now turn our attention to the application of the legal test to the question of responsibility in individuals with congenital mental infirmities. The subject is a very important one, as we deal here not with insanity or qualitative changes of mind which are acquired in adult life, but with quantitative deficiencies inherent to the individual. To this group belong idiocy, imbecility, feeble-mindedness and a host of intermediary, transitional varieties. To this group belong also the deficiencies of a large class of neuropathic individuals.

tions and types which previously had not been suspected. Normal and pathologic psychology in its turn has availed itself of these discoveries and assisted in throwing light on the obscure problems of personality, memory, volition and reason. The conclusions of modern science lead to a broader and more humane consideration of human responsibility. The old traditions and the material interest which are threatened are not the only elements to be considered. The individual himself, his most intimate and most profound beliefs, the principles of his life in all its manifestations, in the domain of his individual consciousness as well as in their application to social discipline—all these questions are taken into consideration by modern science in its effort to arrive at a proper appreciation of mental responsibility.

Unfortunately the new investigations do not always bear the fruit which could and should be expected. One of the principal reasons is the fact that the studies of the subject are ignored by those who create the laws and those who administer justice. They view exclusively the social side of the law and are not at all interested in psychologic and medical studies which present a different concept of criminality and of the criminal himself. It is true that penal legislation and legal medicine are distinct and separate sciences, but positive criminology must rely on both branches of human knowledge. An intimate unity of these two sciences is an indispensable and an essential condition of progress. Mathematics is a rational science, physics is an experimental science; a union of the two helped to reveal the essential phenomena of matter. Chemistry and medicine are also distinct sciences, but Pasteur's work built the bridge between the two. Psychology finds its elements in mental pathology and physiology. Modern philosophy is bound to look for assistance in medical sciences.

Criminology has for its object the formation of positive laws concerning crimes and the discovery of remedies for them. With this object in view it searches the truth wherever it can be found and takes from medical and legal sciences data which it needs to form a scientific foundation. By the union of the two sciences the old and too narrow boundaries of human conception of liberty and mental responsibility will be broken and progress will be assured.

An attempt in this direction is presented in the present essay, which is based on a personal experience in the courts of the State of Pennsylvania.

In a number of instances of civil and criminal cases in which the question of responsibility was involved the main issue consisted of the test of "right and wrong." Every other element has been invariably eliminated by the skilful attorneys and even by some judges. It seemed in many cases that the criminals' legal knowledge of right and wrong was all that was necessary for determining the question of whether they were mentally responsible or not. The expert has not been permitted to enter into any explanation and to refer to any facts of the criminal's life, character, demeanor or to facts of marked hereditary nature indicating abnormality of mental processes or insanity, feeble-mindedness, imbecility—all showing complete or limited responsibility. Mentally abnormal individuals, as we shall see later, may know the distinction between lawful and unlawful acts and still be not mentally responsible.

The first test of wrong and right was proposed in 1843 by fifteen judges in England. It appears in the phrases "unable to distinguish right from wrong," or to discern "that he was doing a wrong act," or was "ignorant that he was committing an offence against the laws of God and nation." In 1846 Chief Justice Gibson, of Pennsylvania, said:[1]

> A man may be mad on all subjects; and then, though he may have glimmerings of reason, he is not a responsible agent. This is general insanity; but if it be not so great in its extent or degree as to blind him to the nature and consequences of his moral duty, it is no defence to an accusation of crime. It must be so great as entirely to destroy his perception of right and wrong, and it is not until that perception is thus destroyed that he ceases to be responsible. It must amount to delusion or hallucination controlling his will, and making the commission of the act in his apprehension a duty of overruling necessity.

Speaking further on partial insanity, the judge remarks:

> Insanity may be confined only to one particular subject, and then the individual continues to be a legitimate subject of punishment, although he may have been laboring under an obliquity of vision; a man whose mind squints, unless impelled to crime by this very mental obliquity is as much amenable to punishment as one whose eye squints.

Afterward in 1858 the judge said:[2]

> So far as the act is concerned, insanity must be so great in extent and degree as to blind him to the natural consequences of his moral duty and must have utterly destroyed his perception of right and wrong.

The legal conception of insanity as defined in these few examples had such a strong hold that it could not be shaken. It continued to form the basis of decisions and rulings in subsequent cases.

In spite of advancement of scientific research in the field of mental science and psychology, the results are totally or greatly ignored by some jurists. In many instances they continue to follow the old traditional path, no matter how unscientific, irrational and inhumane the test of right and wrong may be.

In discussing the various forms of mental disease we shall see that a person in committing a crime may realize the enormity and the lawlessness of the act and still be irresponsible for the act. The so-called moral insanity presents the most striking example of impracticability of application of the generally accepted test. Here the abnormal moral conceptions, the extraordinary propensities, eccentricities, the abnormal conceptions of obligations, etc., may be present a long time together with the proper conception of wrong in a criminal act. Shall such an individual be considered entirely responsible?

In sane life the knowledge of right and wrong is not the only factor that affects the free choice of our actions. We have to count also with impulses, with powerful motives. The power of restraint is in a certain relation with ideas and feelings which are opposed to the impulses. Will-power may suppress the latter. Will-power depends on the power of deliberation and self-control. The latter two factors differ immensely in various individuals. In normal life consequently an overwhelming pressure of external circumstances may sometimes and in some individuals remove to the background and even check completely the power of restraint or of self-control, although the distinction between right and wrong is totally preserved.

The pathologic states of mentality are characterized precisely by a more or less marked diminution or even complete abolition of the power of deliberation, of will, of self-control, and yet the ability of understanding that an act is morally wrong or forbidden by law may be present in its integrity.

---

[1] Commonwealth vs. Mosler, 4 Barr, 264, 1846.

[2] Commonwealth vs. Ferth, 3 Phila. 105, 1858, per Ludlow, J.

Let us, therefore, consider in detail the various forms of mental abnormality in connection with the principle of right and wrong.

In melancholia, homicide occasionally occurs. The individual kills because he does not wish the victim to suffer through his sins. The delusion is usually intensified by hallucinations and the latter hasten the act. Here an insane motive prompts the action and the morbid condition has affected the mind generally so that the impulse of action is derived from the state of feeling and thought. The distinction between right and wrong is impossible.

In mania all the functions are exalted and there is more or less marked diminution of controlling power, so that even slight stimuli may lead to intense actions. In ordinary cases the intellect is not affected and the individual committing an unlawful act may know perfectly well the significance of the act and still, because of the decrease or complete disappearance of inhibition power, which forms the essential characteristic feature of the disease, the impulse is overwhelming. It is, however, true that in pronounced cases or in chronic cases there is an intellectual weakness and a confusional state so that the maniacal patient is then incapable of understanding the nature of his acts.

In no form of mental disorder can the legal test of right or wrong lead to more errors than in a certain class of paranoia. In the hallucinatory variety of this psychosis the impulse to poison, to kill, to massacre, to persecute is prompted by the hallucinatory images and the power of discriminating between a lawful and unlawful act is distinctly abolished. In another variety of paranoia, the individual is to all appearances a reasonable being, capable of comprehending an ordinary conversation, capable of discussing various subjects, and still on one particular subject his judgment is paradoxical and abnormal. He may then fail to exhibit in a long conversation evident signs of mental derangement until the subject of his main or only delusion is touched on. This is the so-called "partial insanity." Jurists and laymen then say that that individual's insanity is confined to a particular subject, the man being sane in every other respect. Sometimes they say that the man's criminal act is only the expression of depravity or of passion which in their eyes does not appear to differ materially from those of sane men and consequently the criminal impulse is simply an incident in the life of a sane man who is expected to overcome it. Such an individual, in spite of his apparent sane demeanor and attitude not infrequently labors under a special and fixed delusion which he conceals quite skilfully. He silently contemplates revenge and in the most careful and deliberate manner he plans its execution. The criminal knows perfectly well that he is committing an offence against the law and that he may be punished, but his act is prompted by an irresistible impulse which is the direct result of his delusive ideas. In this class of cases one must consider the true factors affecting the criminal act, viz.: the delusion, the defective power of inhibition and the abnormal feeling. These are the only elements that affect the power of free action. They alone must be taken into account in our attempt to appreciate a paranoiac's action. The legal view is totally inadequate and narrow, as alongside of those morbid elements the realization of an unlawfulness of an act may be well preserved.

In general paralysis of the insane the question of responsibility may come up during any of the periods of the disease. When the dementia is pronounced, there can be no doubt as to the patient's incapacity of distinguishing wrong from right. But before mental failure becomes accentuated, the individual may present only peculiarities of conduct, tendencies to deception, fraud or theft, extravagant mode of living, suspicious relations to his surroundings and in addition to this some physical signs also—all showing clearly the development of paresis. While committing an unlawful or criminal act the patient may be fully aware of the illegality of such act and of the consequences he will have to suffer for such an act; nevertheless the man is insane in the true sense of the word and the criminal act itself, as well as the above abnormalities of disposition, character, conduct, is an early sign of the disease. If the test of right and wrong is strictly applied to such cases, the man must inevitably be punished and when the crime is assault and murder he will be hung or electrocuted. Such a procedure is unquestionably a miscarriage of justice and essentially inhuman. A paretic at any of the phases of his disease is insane: his power of control, his feeling, his deliberation are fundamentally defective, abnormal and consequently his acts are the result of sudden morbid impulses. These are the immediate causes of his irresponsibility, but not the legal principle of right and wrong. Illegal acts are sometimes the first manifestations of the disease and the peculiar features with which they are sometimes surrounded lead us to the right road for a diagnosis.

Senility is not necessarily a cause of irresponsibility. Many individuals preserve the integrity of mental faculties until a very old age. When the senile involution has progressed so far as to abolish completely the faculties, all responsibility disappears. But the involution may be slow, irregular and at the same time progressive, and in such cases there may be a long phase during which the moral conceptions, obligations, the sense of propriety, affection may gradually undergo radical changes so as to lead to most unexpected acts. A senile dement, no matter how slight his dementia may be, is apt to commit the most extraordinary acts. In making a will, for example, he may be guided by petty motives which are easily aroused; anger, desire for revenge, jealousy can be stimulated with the greatest facility, and a will signed by a senile dement may express the most extraordinary, most unjust, most inhumane wishes. As he is easily influenced, he may change his will at each change of his humor. In spite of this variability of actions, he may be fully aware that he is doing a wrong act. He may fully realize the injustice done to persons whom he deprives of the worldly goods and he will, therefore, be legally responsible. The test required by law is positive here, but is it just? A senile dement is in a pathologic state; he is insane in the most proper sense of the word. Scientifically he can not be considered responsible, and consequently by relying exclusively on the classical legal test, injustice is easily done.

Let us now turn our attention to the application of the legal test to the question of responsibility in individuals with congenital mental infirmities. The subject is a very important one, as we deal here not with insanity or qualitative changes of mind which are acquired in adult life, but with quantitative deficiencies inherent to the individual. To this group belong idiocy, imbecility, feeble-mindedness and a host of intermediary, transitional varieties. To this group belong also the deficiencies of a large class of neuropathic individuals.

who present during life episodic psychasthenic manifestations, such as 'phobias, obsessions, abulia, *folie de doute, délire de toucher,* etc.

The idiot and the low-grade imbecile can not be expected to realize the enormity and the lawlessness of a criminal act, but when an attempt is made to apply the classical legal test to cases of milder intellectual weakness, to the large class ranging between imbecility to simple backwardness, one is bound to appreciate its inapplicability.

This class of individuals present, besides a certain degree of intellectual inferiority, a certain inaptitude to acquire knowledge, to perform mental operations of a more or less complex nature, but also and particularly an inherent deficiency of inhibitory power. Their whole existence is composed of incidents of an instinctive nature, as the instinct predominates in them and, therefore, their actions are invariably the result of impulses. Some of these individuals may be fully aware of the illegality of a certain act, they may fully realize that murder, assault, arson, deception which they sometimes commit are morally wrong and punishable by law, and yet they can not for the above reasons be held totally accountable for their actions. Is it an act of judicial wisdom to hang or to send to the electric chair or else imprison for life, if they have committed capital crimes, individuals who present an arrested mental development of various degrees, also the so-called peculiar, eccentric, queer individuals, those who present episodically during life obsessions, 'phobias or other deviations from normal cerebral functions—otherwise speaking individuals with an abnormal psychic make-up, although not insane in the proper sense of the word—is it, I say, an act of justice to consider them completely responsible and consequently inflict a corresponding severe punishment for only this reason, that they can discriminate legally wrong from right?

Régis has recently said:

> Mankind unfortunately can not be divided from a psychologic standpoint into two distinct categories, viz., one side mentally sane or totally responsible and on the other side, insane and totally irresponsible. Between the two there is a large province, the so-called intermediary zone populated by individuals tainted in various degrees and consequently presenting very different degrees of responsibilities. Although it is impossible to measure the latter by millimeters, it is nevertheless possible to establish for them from this standpoint an ascending or descending scale and consider quite precisely three progressive degrees, viz., slightly, sufficiently and very largely limited responsibility.

The group of cases which I have just discussed is, scientifically speaking, composed of individuals whose responsibility can by no means be total; it must be limited. The latter is not a subterfuge of the expert, but a scientific fact established on scientifically accurate clinical observations which can not be denied. It is, therefore, evident that the legal test of wrong and right can not be applied to those cases, and if it is applied, as it is frequently done, the results are bound to be disastrous as far as the administration of justice is concerned.

Mental disturbances caused by intoxication with alcohol, opium and other poisons deserve some consideration with regard to the medicolegal test. Alcohol is a very powerful etiologic factor of criminality. One may say that it plays a very important rôle in the majority of committed crimes.

When a crime is committed by an individual while in a state of intoxication, several possibilities must be considered, viz.: whether the intoxication occurred in an individual with a pre-existing mental affection or without it, also whether the intoxication was intentional for the purpose of committing the crime during that state. It stands to reason that the delirious or confusional or stuporous states caused by an intoxication *per se* render the affected person irresponsible. It is impossible to expect from an acutely intoxicated individual a clear conception of right and wrong. His reasoning, judgment and discriminatic [illegible] and quantitatively disturbed. If, [illegible], [illegible] of right and wrong is the legal criterion of responsibility or irresponsibility, grave mistakes must be committed; a criminal will become intoxicated intentionally and then claim excuse for his act in the drunkenness; if he is acquitted or only slightly punished on that ground the community will suffer an injustice. On the other hand, an inability to distinguish right from wrong means insanity from a legal standpoint. A man who became incidentally intoxicated can not be considered insane and committed to an asylum. It is, therefore, evident that from every standpoint in such cases the law can not rely on its classical test in determining the question of responsibility.

Chronic intoxication (alcoholism, morphinism, etc.) are characterized chiefly by a gradual progressive mental enfeeblement. But before the latter becomes pronounced there may be evident changes in the affective sphere of life. Irritability, susceptibility, outbreaks of anger, indifference, loss of affection for the near and dear ones—may all be the [illegible] These manifestations may be more [illegible] intellectual enfeeblement which in some cases progresses very slowly. Crimes or any illegal act may be committed during any of the phases of chronic alcoholism, morphinism or other intoxications. They may, therefore, occur at a stage when, in spite of the gradual deterioration, the faculty of discrimination is preserved to a more or less sufficient extent so as to know that his acts are wrong or right. Nevertheless the individual is in a diseased condition, his organs and tissues are undergoing degeneration. His demeanor, attitude, relation to others, show that his volition suffers, his power of inhibition is deficient. Such an individual, even with preservation of a large part of the faculty of discrimination, can not be held totally responsible. The legal test applied to such cases will naturally lead to a miscarriage of justice. Chronic alcoholism, morphinism or other intoxications at any of their phases are veritable diseases requiring medical supervision.

A very important and serious problem confronts alienists and jurists in deciding the question of responsibility of a person during the state of lucid intervals. For the purpose of simplification I embrace under this term intermissions, viz.: apparently normal intervals between individual attacks of a certain mental affection; also brief periods of apparent lucidity of mind occurring in the course of any psychosis, finally the remissions, viz., an attenuation of symptoms for a more or less long period.

A question arises: How much is the legal test of wrong and right justifiable in cases of criminal acts committed during lucid intervals? There can be no doubt that at that time the discrimination between lawful and unlawful acts is possible; consequently should the individual's responsibility be then considered complete?

A person once affected with acute melancholia or acute mania may have recurrences at intervals of months' or years' duration. The question is whether the person thus affected can be considered as entirely cured during those intervals. Experience teaches that the degree of recovery and its duration are variable. When we are in presence of an individual with a history of several attacks of a certain mental affection, who has just recovered from one, perhaps to enter another, and who happened to commit a criminal act during the interval—are we justified in considering him completely normal and perfectly responsible only because he is able to realize legally the criminality of his act? The fact of his being repeatedly subjected to attacks of mental derangement, even at long intervals, is a proof of the individual's mental and moral make-up being abnormal and pathological. These remarks are particularly applicable to the lucid moments proper, which occur in the course of a certain psychosis and which are brief or very brief in duration. Such lucidity is only ephemeral, more apparent than real. A civil act such as a will, for example, executed or altered during the lucid interval, should not be considered valid, in spite of the individual's knowledge of the wrong he did to those who are the interested parties.

During remissions, particularly those of paresis, various degrees of improvement are observed in the mentality. The improvement may in some cases be so marked as the patients appear perfectly normal. But it must be borne in mind that a remission is only a temporary amelioration of the psychic manifestations, but in no respect a recovery. In paresis, for example, alongside of apparent lucidity of mind, all or some of the sensory and motor symptoms of the disease, always persist. The disease is essentially progressive and not curable, in spite of great improvement that may occur in the psychic sphere. If, therefore, an illegal act is committed by a paretic during a remission, when he is able to distinguish between right and wrong, should he be considered as a normal individual and consequently held totally accountable for his act? From a physiologic standpoint a paretic is at no stage of his affection responsible, and if the legal test is applied to him he must be imprisoned and severely punished. Such a procedure is certainly a miscarriage of justice, as paretic must be housed in asylums or hospitals instead of in prisons.

There are two other affections in which the legal conception of right and wrong, when applied during apparently lucid intervals, may lead to disastrous consequences. I mean dipsomania and epilepsy. As it is well known, the first is characterized by an episodic irresistible desire to absorb alcohol. The dipsomaniac in the early stages of his infirmity presents apparent lucidity of mind and control of his faculties between the attacks of craving for drink. Dipsomania is always the result of a chronic use of alcohol. Whether in its early or later stages, it is a diseased condition and impulsive acts of any nature are likely to occur in such individuals. It is true that in an advanced period there is marked intellectual enfeeblement. In earlier stages the power of reasoning is sufficient for a realization of the criminality of an act, but, being affected by a malady which interferes with his normal life, although paroxysmally, such an individual can not be considered totally responsible; the responsibility is naturally only limited. The legal test consequently is not applicable to cases of this nature; if it were, the prison or gallows would take the place of hospitals. A dipsomaniac's chief characteristic is a pathologic state of inhibitory power.

Turning our attention to epilepsy, we find that the legal application of the usual test encounters some difficulty. In epilepsy a convulsive attack may be followed by an impulsive act of which the patient has no recollection; and then an epileptic seizure itself may consist of intellectual disturbances instead of the habitual muscular manifestations; instead of convulsions there may be unconscious aggressive acts; the patient may steal, rob, attack or kill. The irresponsibility in such cases is, of course, absolute. But when violent acts are committed by epileptics in the lucid intervals between the seizures, viz., when they are capable to appreciate the lawlessness and the consequences of such acts, the legal test of right and wrong appears to be the proper test. Nevertheless, if we consider the permanent state of morbid irritability which renders epileptics more than normal individuals predisposed to outbreaks of anger, of violence (and this is particularly true in cases with frequently occurring seizures); if we also consider that fact that the majority, if not all, epileptics are neuropathic individuals whose unstable nervous system is predisposed to various functional nervous disorders, we can conceive that epileptics between the seizures are only incompletely accountable for their acts; their responsibility must necessarily be limited and a strict application of the legal test is not an act of justice.

CONCLUSIONS

The foregoing review of various mental abnormalities leads directly to this deduction that in cases of insanity or other forms of mental deviation there may be a fair understanding of a morally wrong or right act and of a legal or illegal act, and yet there may be a pathologically insufficient controlling force. Every student of psychiatric problems, every psychiatric clinician knows that these two conditions may coexist, and the absence of the first does not exclude insanity or other psychic abnormality, and consequently does not exclude irresponsibility. Indeed, in some cases the absence or diminution of the faculty of inhibition predominates in the mental picture—or forms the entire symptomatology of the disease. The deviation in the manner of thinking, feeling and acting may not be present in its entirety, but may be dissociated in its original elements. The insane or abnormal feeling is just as important as the insane or abnormal thinking. In a large number of cases the change of feeling may for a long time be the *earliest or the only manifestation of disturbed cerebral* functions and this morbidly altered feeling may be the direct motive for abnormal or criminal actions. Intellectual capacity alone, therefore, can not constitute a proper criterion in consideration of criminal acts, and if the legal test refuses to take into account anything else but intellectual capacity it is radically unscientific and can not properly serve the ends of justice; judicial errors will invariably occur. The whole problem of a test in such cases depends, therefore, on the acceptance of the scientific data accumulated and elaborated from a large number of clinical observations.

To diagnose a mental malady special knowledge is indispensable. The latter is absolutely necessary for the proper appreciation of those cases in which illegal acts are committed by individuals, with all the evidences of reasoning, premeditation and reflection, who are nevertheless lunatics or otherwise mentally abnormal. It is indispensable because sometimes alterations in the psychic sphere are apparently very slight and yet are in reality considerable but concealed. It is indispensable because discovery of important elements for appreciation of certain crimes which are peculiar or unusual in their nature can be made by men who have had a special experience in psychologic analysis. Examination of these cases must be made not only in relation to the circumstances which preceded, accompanied or followed a certain lawless act, but also and particularly in relation to the entire previous and present medical history of the individual himself in all its minutest details, as they all are important in appreciation of his mental make-up. Every clinician is well aware of the importance of all these details. Reliance on one clinical element at the exclusion of all others is contrary to the scientific spirit. Adherence to such a procedure must invariably lead to errors, and this is especially observable in cases in which mental operations are involved. The law that holds a person accountable for his acts only on the basis of discrimination between right and wrong is wholly inadequate, because it is not based on accurate data gathered from clinical experience. The jurist must cooperate with and, I should say, almost entirely rely on the alienist. But the latter must be given the greatest latitude in presenting all the details concerning the medical history of a given case. Under no consideration should he be restricted to limit his opinion as to the exclusive right-and-wrong test. If the expert is ordered to confine himself exclusively to the determination of whether the accused individual is capable to distinguish legally right from wrong, he is then forced to omit extremely important facts which, as we have seen above, constitute sometimes real elements of alienation. Thus a lunatic, in the proper medical sense of the word, will be condemned while in a state of irresponsibility.

Personal experience in the courts of Pennsylvania has convinced me that this test is very strongly adhered to in the majority of instances. In view of our present knowledge of normal and pathologic processes in the psychic sphere, in view of our experience in the manner and methods of the proper appreciation of abnormal mental operations, in view of the evident injustice that may be done to some individuals who are rather subjects for treatment in hospitals than to be placed in prisons and considered as criminals—for all these reasons I believe a revision of the old classical test of right and wrong is strongly required. A combined effort of medical and legal experts must be made for mutual enlightenment on this important subject and avoidance of the repetition of grave errors of the past will thus be accomplished. Human liberty and responsibility are two most serious elements of life that can not be dealt with in a purely technical manner. They must be viewed from the standpoint of the broadest principles governing the interrelation between the individual and the community.

1430 Pine Street.

ABSTRACT OF DISCUSSION

Dr. Charles W. Hitchcock, Detroit: I had occasion during the past year to review the laws of a number of our states regarding the matter of mental responsibility and in the ultimate analysis it seems to me that a great loophole is afforded to the insanity defense by the breadth of the laws, which almost uniformly permit any proof of insanity as an adequate defense for crime, instead of going further and inquiring not only whether the prisoner is insane, but whether he is so insane as to be irresponsible for his act, and is his act in any way the direct fruit of his insanity, if that be proved.

Dr. A. C. Brush, Brooklyn: The question of impulsive acts in insanity is one of grave social importance. It is held in the laws of the state of New York, 157 N. Y., by Justice O'Brien, that, although there may be such a form of insanity recognized, that the patient knows the nature of his act and deplores and fears its consequences, yet he is impelled by an impulse over which he has no control to perform the prohibited act. Whatever authority there may be in medicine there is none in law, and that is a wise decision from a sociologic standpoint; otherwise any prisoner might claim that he had an irresistible impulse to commit crime, and consequently society would be at the mercy of the criminal. It is not the fault of law, but the fault of medicine primarily. So long as we can not define insanity, can not define a dividing line between the sane and the insane, for there is none, the law must have some standard to set up for the defense of criminal cases, and that standard is still the old wild beast theory, and it must remain so until medicine evolves some more modern standard. Lawyers and judges are perfectly willing to accept any new standard if we can furnish it; but as yet we have failed, and until that is done, until we ourselves can evolve some more carefully and clearly defined rule, the present one must prevail.

THE STABILITY OF TYPE OF THE TUBERCLE BACILLUS

A STUDY OF THE TYPE OF CULTURES FROM OLD CUTANEOUS TUBERCLES OF BUTCHERS *

ALFRED F. HESS, M.D.
NEW YORK

It is now generally conceded that the tubercle bacillus of cattle at times incites tuberculosis in man. This conclusion has been definitely established only through the possibility of distinguishing between a bovine and a human type of bacillus, and through employing this method and isolating the bovine type of organism from human tuberculous infections. The studies thus far carried out in different countries, using the same methods of differentiation, agree in charging the human bacillus with a marked preponderance of infections. In this connection, however, there is one disturbing criticism that is now and again brought forth to shake the confidence reposed in these conclusions, based, as they are, on the differentiation of the types of bacilli. It is asserted by some capable workers that it is possible for the bovine bacillus to be so altered by years of sojourn in the human tissues that its essential characteristics become altered and it simulates the human type of bacillus. Without doubt, if this metamorphosis can readily take place, some of those infections which we now believe to have been of human origin may well have had their source in bovine infections of years ago, and it is to no purpose to designate them as human. In fact, if this be so, the entire method of differentiation which has accomplished so much in the past decade, and promises so much more in the practical and theoretical study of tuberculosis, would have to be regarded as not only unreliable, but misleading.

The main difficulty in studying this question in man is that we are rarely certain of the nature of the original infection and accordingly can not judge of the change of type. Our main reliance is generally circumstantial evidence. An exception to this rule, however, is furnished by those few cases of inoculation tuberculosis in which the bovine source of infection is definitely known. I have with difficulty found two cases of this nature, both in slaughter-house workers, and report a study of them coupled with some other experiments relating to the stability of the types of tubercle bacilli.

Case 1.—This man had been employed in his present trade for seven years. Four years ago, while slaughtering an animal,

---

* From the Research Laboratory, Board of Health, New York.

he cut the middle finger of his right hand on the pointed end of a rib. He gave no thought to this injury until he found that it was slow to heal; he then merely applied various ointments. Gradually a nodule appeared at the site of the wound which assumed its present condition. He was aware of the tuberculous nature of this nodule, and in fact directed me to another worker who had the same skin lesion. I shall not enter into a minute description of the appearance of this nodule. It was of the size of a large pea, brownish-red and very firm in consistency. The glands at the elbow and axilla were not enlarged. The general health of the man was excellent.

CASE 2.—This case was very similar to the previous one. This man, while slaughtering a tuberculous cow, cut himself with a knife across the knuckles. This accident happened about six years ago. He remembered the date, as he was forced by this disability to quit work for some weeks and to enter the employment of another firm. As in the previous instance, a nodule appeared at the site of injury. The nodule was situated over the fourth left metacarpal joint, and resembled the tubercle described in the previous case, except that its surface was rougher and papilliform. This man also was healthy to all appearances; a large hard epitrochlear gland was palpable at the right elbow.

Both of these men were induced to have their nodules excised. After excision the surface of the growths was removed, and they were thoroughly washed in sterile water. Two guinea-pigs were inoculated subcutaneously with each growth. All four animals developed tuberculosis. It is not necessary for me to give in detail the method of isolating tubercle bacilli from the tissues or the criteria for differentiating the types. The method employed was that now generally followed and made use of by me in previous studies.[1] The cultural growth from these two cases proved to be very similar; in fact, I could not distinguish between them. They both grew sparsely on egg media. They also showed a high degree of virulence for rabbits, producing a generalized tuberculosis when inoculated intravenously in the dose of one milligram. In other words, they were typically bovine.

Before discussing these results I shall describe an experiment undertaken with the object of transforming the bovine type of the tubercle bacillus into the human type. An attempt was made to produce a culture medium resembling in its composition as closely as possible the human tissues. From the outset the inherent variance between an artificial culture medium and the living tissues was clearly realized. For this purpose, however, what may be termed "human-placenta glycerin broth" was devised. Human placenta was obtained under strict aseptic precautions and from this a broth was made, treating the placenta just as the beef is treated in preparing the broth for common use. One per cent. peptone, 0.5 per cent. salt and 5 per cent. glycerin were added. The entire preparation of this culture medium was conducted under as sterile conditions as possible. In order not to destroy the complement of the human placenta, heat was applied only to 55 C. It was possible in most instances to obtain a sterile broth by means of filtration through a Berkefeld filter.

Two bovine strains of known virulence, one of them having been under artificial cultivation for many years, the other only recently isolated, were grown on this culture medium for nine months, comprising eight generations. At the end of this period their virulence for rabbits was found to be as marked as at the beginning, showing that in this respect they had not approached the human type. In fact, the only change that was noted was one to be anticipated from artificial cultivation of any nature, namely, a greater facility of growth in the case of the strain which had been the more recently isolated. As this experiment was very laborious and promised so little, it was discontinued.

The question of the stability or variability of the types of tubercle bacilli has been discussed so frequently that I shall not review the testimony. In connection with this report, however, a few words on this subject seem in place. From the outset it should be realized that this question has a practical as well as a theoretical aspect, and that the two need not be in absolute accord. The former considers whether it is in any way possible by natural or artificial means to convert one type of bacillus into another type; the latter, whether the bacilli isolated from man and designated as human have been converted in his tissues from an original bovine type. These two points of view must not be confused. It is true that it has been demonstrated that under artificial cultivation strains may be greatly changed in their cultural and biologic characteristics. Indeed, a culture isolated almost ten years ago from a cow, and kindly sent to me by Prof. Leonard Pearson, I recently found to simulate the human type both in luxuriance of growth and diminished virulence for rabbits. Even after this long period of artificial cultivation, however, its virulence was still greater than cultures of the human type. Another bovine culture of about the same age was found to be markedly virulent for rabbits.

Such experiments clearly can not be translated into practical evidence on this question. Again, it may be advanced that experiments have been reported showing a conversion of human into bovine bacilli by means of passage through cattle; or of bovine into avian bacilli by means of passage through birds. Even if we accept these interpretations, however, and forego the criticism that has been levelled at them justly by others, we find these experiments to be very few in number and far outweighed by the many others in which no conversion of type was effected. When we consider the practical side of this question and draw our arguments from what we know of tubercle bacilli in man, the following should be borne in mind: It is true that atypical strains have been isolated by many investigators, strains neither typically human nor bovine. This intermediate group may in part be accounted for by attributing the variation to a change of environment, for example, of bovine bacilli in the new environment of human tissue. These atypical strains, it should be remembered, are exceptional; among three bovine and four human strains which I have isolated from man none belong to this category. Furthermore, this deviation from type can not be regarded as evidence of the possibility of a complete change of type. In this connection, it is worthy of note that typical bovine bacilli have been isolated from calcareous lymph nodes of human beings; in such instances the bovine bacilli must have existed in the human tissues for years without undergoing transformation. It has never been shown that the older the tuberculous lesion the less the likelihood of isolating bovine bacilli from man; and yet this corollary should obtain if the bacilli are readily converted in the human tissues. The question may be approached from another point of view. It is well known that no case of primary pulmonary tuberculosis has been indisputably proved to have been incited by the bovine bacillus. These cases form the great mass of tuberculosis and have been studied more than all others. If this form of disease is due in some instances to a bovine bacillus which has been transformed in the human body, we should at least occasion-because discovery of important elements for appreciation of certain crimes which are peculiar or unusual in their nature can be made by men who have had a special experience in psychologic analysis. Examination of these cases must be made not only in relation to the circumstances which preceded, accompanied or followed a certain lawless act, but also and particularly in relation to the entire previous and present medical history of the individual himself in all its minutest details, as they all are important in appreciation of his mental make-up. Every clinician is well aware of the importance of all these details. Reliance on one clinical element at the exclusion of all others is contrary to the scientific spirit. Adherence to such a procedure must invariably lead to errors, and this is especially observable in cases in which mental operations are involved. The law that holds a person accountable for his acts only on the basis of discrimination between right and wrong is wholly inadequate, because it is not based on accurate data gathered from clinical experience. The jurist must cooperate with and, I should say, almost entirely rely on the alienist. But the latter must be given the greatest latitude in presenting all the details concerning the medical history of a given case. Under no consideration should he be restricted to limit his opinion as to the exclusive right-and-wrong test. If the expert is ordered to confine himself exclusively to the determination of whether the accused individual is capable to distinguish legally right from wrong, he is then forced to omit extremely important facts which, as we have seen above, constitute sometimes real elements of alienation. Thus a lunatic, in the proper medical sense of the word, will be condemned while in a state of irresponsibility.

---

[1] Hess: Cultures of Tubercle Bacilli isolated from Milk, Jour. Infect. Dis., June, 1909, p. 329.

Personal experience in the courts of Pennsylvania has convinced me that this test is very strongly adhered to in the majority of instances. In view of our present knowledge of normal and pathologic processes in the psychic sphere, in view of our experience in the manner and methods of the proper appreciation of abnormal mental operations, in view of the evident injustice that may be done to some individuals who are rather subjects for treatment in hospitals than to be placed in prisons and considered as criminals—for all these reasons I believe a revision of the old classical test of right and wrong is strongly required. A combined effort of medical and legal experts must be made for mutual enlightenment on this important subject and avoidance of the repetition of grave errors of the past will thus be accomplished. Human liberty and responsibility are two most serious elements of life that can not be dealt with in a purely technical manner. They must be viewed from the standpoint of the broadest principles governing the interrelation between the individual and the community.

ABSTRACT OF DISCUSSION

DR. CHARLES W. HITCHCOCK, Detroit: I had occasion during the past year to review the laws of a number of our states regarding the matter of mental responsibility and in the ultimate analysis it seems to me that a great loophole is afforded to the insanity defense by the breadth of the laws, which almost uniformly permit any proof of insanity as an adequate defense for crime, instead of going further and inquiring not only whether the prisoner is insane, but whether he is so insane as to be irresponsible for his act, and is his act in any way the direct fruit of his insanity, if that be proved.

DR. A. C. BRUSH, Brooklyn: The question of impulsive acts in insanity is one of grave social importance. It is held in the laws of the state of New York, 157 N. Y., by Justice O'Brien, that, although there may be such a form of insanity recognized, that the patient knows the nature of his act and deplores and fears its consequences, yet he is impelled by an impulse over which he has no control to perform the prohibited act. Whatever authority there may be in medicine there is none in law, and that is a wise decision from a sociologic standpoint; otherwise any prisoner might claim that he had an irresistible impulse to commit crime, and consequently society would be at the mercy of the criminal. It is not the fault of law, but the fault of medicine primarily. So long as we can not define insanity, can not define a dividing line between the sane and the insane, for there is none, the law must have some standard to set up for the defense of criminal cases, and that standard is still the old wild beast theory, and it must remain so until medicine evolves some more modern standard. Lawyers and judges are perfectly willing to accept any new standard if we can furnish it; but as yet we have failed, and until that is done, until we ourselves can evolve some more carefully and clearly defined rule, the present one must prevail.

THE STABILITY OF TYPE OF THE TUBERCLE BACILLUS

A STUDY OF THE TYPE OF CULTURES FROM OLD CUTANEOUS TUBERCLES OF BUTCHERS *

ALFRED F. HESS, M.D.
NEW YORK

It is now generally conceded that the tubercle bacillus of cattle at times incites tuberculosis in man. This conclusion has been definitely established only through the possibility of distinguishing between a bovine and a human type of bacillus, and through employing this method and isolating the bovine type of organism from human tuberculous infections. The studies thus far carried out in different countries, using the same methods of differentiation, agree in charging the human bacillus with a marked preponderance of infections. In this connection, however, there is one disturbing criticism that is now and again brought forth to shake the confidence reposed in these conclusions, based, as they are, on the differentiation of the types of bacilli. It is asserted by some capable workers that it is possible for the bovine bacillus to be so altered by years of sojourn in the human tissues that its essential characteristics become altered and it simulates the human type of bacillus. Without doubt, if this metamorphosis can readily take place, some of those infections which we now believe to have been of human origin may well have had their source in bovine infections of years ago, and it is to no purpose to designate them as human. In fact, if this be so, the entire method of differentiation which has accomplished so much in the past decade, and promises so much more in the practical and theoretical study of tuberculosis, would have to be regarded as not only unreliable, but misleading.

The main difficulty in studying this question in man is that we are rarely certain of the nature of the original infection and accordingly can not judge of the change of type. Our main reliance is generally circumstantial evidence. An exception to this rule, however, is furnished by those few cases of inoculation tuberculosis in which the bovine source of infection is definitely known. I have with difficulty found two cases of this nature, both in slaughter-house workers, and report a study of them coupled with some other experiments relating to the stability of the types of tubercle bacilli.

The two cases of cutaneous tuberculosis which I report claim some degree of interest because they constitute bovine infections occurring in adults. The fact that they remained localized should not be attributed to the low degree of virulence for man of the bovine bacillus, as it is well known that cutaneous affections due to the human type of bacillus, such as lupus or the "anatomic tubercles" contracted in the dissecting-room likewise do not tend to systemic invasion. Their main significance, however, lies in the fact that they furnish exceptional instances of bovine tubercle bacilli which have lived in the human tissues for many years without acquiring characteristics of the human type. From this point of view they constitute evidence against the conversion in the human tissues of bovine bacilli into human tubercle bacilli. It would be interesting and of undoubted value if those who have access to similar

SYPHILITIC PSEUDOPARALYSIS*

L. T. ROYSTER, M.D.
NORFOLK, VA.

Few diseases have been studied with greater care than syphilis, nor have their individual manifestations been noted more in detail, and I am perhaps not far wrong in saying that the literature of medicine is more voluminous on syphilis than any other single disease. This is not a matter for surprise, for no disease has a more widespread influence on human ailment; yet it appears to me that, while the acquired form of syphilis is reasonably well understood, we are still lamentably ignorant of the significance of the hereditary form as it relates to many of the obscure conditions of childhood and young adult life. I therefore deem it not inadvisable to draw attention to just one manifestation of this taint and to report two cases illustrative of several observations which have been made on this class of case.

Syphilitic pseudoparalysis is a manifestation of inherited syphilis which exhibits itself during the first few months of life in a failure, disinclination or inability to move one or all of the extremities, and is variously alluded to in the literature as syphilitic pseudoparalysis, Parrot's paralysis, or merely described under the pathologic condition syphilitic epiphysitis, and belongs under the general class of osteochondritis.

There are various gross appearances dependent on the stage or degree of cartilaginous inflammation. Thus there may be a ring or collar apparent on palpation, partly or wholly surrounding the bone at the junction of the epiphysis with the shaft (usually upper) due to proliferation of the cells, or there may be a distinct separation at the same point due to absorption of the cartilage with accompanying free motion at the false joint thus formed. Or again, there may be complete breaking down of the tissue with pus formation, finally rupturing through the skin forming an open abscess. Such cases, however, are thought to be due to secondary pus infection.

The first symptom to attract attention to this condition is the fact that the child does not move one or all of its extremities. Only one upper extremity may be affected or both arms and both legs. The frequency with which the various extremities are affected does not appear to be settled, and the only observer who reports a sufficient number of cases from which conclusions may be drawn is Bednar, who lists nineteen, as follows: Arms alone, 16 times (does not state whether one or both arms were affected—presumption both); legs only, once, and all limbs twice. While some authors state that it may occur in only one extremity, none cites a case without either both arms or both legs or all four extremities being affected. In case one or both arms are affected the child will lie with them rotated so far inward that the palms face outward. These cases resemble and are in appearance identical with brachial birth paralysis. When the legs are affected, however, the rotation is apt to be outward. Usually the affected limb is in a state of flaccidity, and if the arm is lifted and let fall it will drop again to the same position; or it may be rotated, and if there is separation at the epiphysis it may be moved freely at the point of separation. I doubt if in such cases as this the children ever give evidence of pain, but they certainly have no power of voluntary motion.

In other instances there is a more or less spastic condition, the joint resisting motion and the child crying out with pain on being handled. In addition are the symptoms which I have already described apparent at the joints.

The exact cause of these various symptoms, all accompaniments of the same pathologic process, seems to be as yet undetermined. Sundry theories have been advanced in an attempt to explain the several states of immobility; thus, some consider the flaccidity due to an inability to move on account of separation or absorption of cartilage, some to myositis, others to pain, and still others to involvement of the peripheral branches of the brachial plexus. Each of these may have a basis of fact in individual instances, but are all open to objection when a number of patients are observed, and do not hold true for all cases. Those which I shall report illustrate some of these points very well.

The diagnosis of this condition is exceedingly important since epiphysitis is said to be the most frequent manifestation of inherited syphilis and further because it may be the only evidence of the presence of the taint. There are but four conditions for which it is likely to be mistaken, viz.—scurvy, infantile paralysis, septic epiphysitis and brachial birth

Scurvy is rarely seen befor from the sixth to the fifteenth month—is always bilateral and affects the shafts of the bones, while epiphysitis is located at the extremity, though it is well to bear in mind that cases have been described in which tenderness was present along the shaft as well—and appears rarely after the third month. Infantile paralysis also appears at a later date, is frequently epidemic and the history, onset and course are entirely different. In septic epiphysitis the constitutional symptoms are pronounced and the temperature elevated.

The diagnosis from brachial birth paralysis seems to me to be the most important and presents the greatest difficulties, for, as has been stated before, when the arms alone are affected the picture is more or less typical of Erb's paralysis. It is to be noted, however, that in Erb's paralysis there is usually a history of difficult labor, with traction either with the forceps or with the hands as in delivery of the shoulders, or in lateral traction as in the delivery of the after-coming head in breech cases. It has been known, however, to occur in normal labors. Erb's is usually unilateral, while pseudoparalysis is more apt to be bilateral. (This latter statement is largely inferential since, as stated, I am unable to find positive statements on this point.) The time of the appearance of the immobility of the two conditions may be the same. When separation is present or the characteristic bony ring can be felt, the diagnosis is rendered easy. In Erb's paralysis the electric reaction of degeneration may be present early, whereas in pseudoparalysis, as stated by Holt, the reaction is normal. It is well to bear in mind on this point the statement of Dr. Eustice Smith, that a form of real paralysis is occasionally observed, affecting the branches of the brachial plexus, causing partial or total loss of motion. It is not stated by him whether this paralysis improves under specific treatment. In Erb's paralysis there is a selection of definite groups of muscles and even a sympathetic involvement as shown by narrowing of the palpebral fissure and contraction of the pupil (Bailey). In pseudoparalysis the various groups of muscles are rendered immobile but there is an apparent selection or involvement of the sympathetic.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

In Erb's paralysis slight tumors are sometimes seen at the point of the tear in the nerve fibers. Some patients with Erb's paralysis improve spontaneously, in which event it appears that the diagnosis may become difficult if not impossible. In patients with pseudoparalysis not treated promptly there may be a permanent deformity from partial or complete absorption of the cartilage, and in after life a case of this deformity may again be indistinguishable from the similar deformity resulting from Erb's paralysis, cases of which rarely escape without some deformity. Bailey states that "as a practical fact electricity is rarely necessary in the diagnosis of this form of paralysis, as the flaccid condition of the affected muscles is usually evident before the child is old enough for electrical examination to be feasible." I would again suggest the fact that the diagnosis may not be so easy as this for the reason as stated, that in pseudoparalysis the flaccidity may very closely resemble the condition found in Erb's paralysis.

The following cases illustrate the various points which I have attempted to bring out:

CASE 1.—Colored male 4 weeks old, well developed and nourished; in fact, normal in general appearance, somewhat inclined to be fat. The mother stated that child had appeared all right at birth and up to two weeks of age, when it began to lose use of arms, and that now it made no effort whatever to move them.

Examination.—I found the child lying in its mother's arms apparently comfortable and contented. Both arms hung limp by the sides, and rotated inward to such an extent that the palms faced outward, and at first I thought I had a case of bilateral Erb's paralysis. The arms were freely movable, dropping again to the same position on being lifted and let fall. No attempt was made on the part of the child to move the arms or even the fingers and tickling the palms elicited no reflex. There was apparently a complete paralysis of the entire upper extremity, but not the slightest evidence of pain either on pressure or on motion. The junction of the epiphysis and the shaft of the upper end of the humerus presented a slight enlargement surrounding the bone, barely perceptible owing to the fatness of the infant. There were no discernible blemishes of any kind, in fact, nothing to suggest anything but a healthy infant, except that the spleen was palpable. The temperature was normal, and was at each subsequent examination. I sought out the granny who had presided at the delivery and with difficulty ascertained that the birth had been normal in every particular, of short duration and that this was the mother's fourth child. The cord was not around the neck.

Treatment.—Mercurial inunctions were instituted at once, and after the fourth treatment the child began to move the fingers; in ten days good use of the forearms occurred, and by the end of three weeks the child seemed to be entirely well, including disappearance of thickening of the epiphysis and enlarged spleen. This child died one year later of enterocolitis.

Remarks.—At the time of my first visit I was unable to secure any family history which would aid in a diagnosis. Several months after, however, I had an interview with the father who gave a good history of secondary eruption, following sore on penis, at the time of conception.

CASE 2.—Colored male, 5 weeks old, presented a typical picture of syphilitic infant. He was poorly nourished, had fissures around mouth and anus; skin was dry and scaly, and there was evidence of subsiding pemphigus of palms and soles. Spleen was enlarged, liver apparently was not.

Examination.—The arms hung in the characteristic position already described, no attempt being made at motion, though both arms could be handled and moved freely without evidence of discomfort. In this case the examination of the arms was easy, since the child was thin. A distinct separation could be detected at the upper cartilage on both side with free rotary motion. In this case, as in the first, there was no reflex of the palm, and, in fact, so far as the upper extremities were concerned, it was a reproduction of Case 1 except for the cartilaginous ring. The lower extremity, however, presented a different picture. The legs were rotated outward and were in a state of spasticity and could not be moved on account of the pain thus caused. I could make out no thickening or separation. The legs were rigidly flexed and were exceedingly tender on pressure as well as painful on motion. On tickling the soles of the feet the toes were readily flexed. At no time was there any temperature. There was possibly some tenderness along the spine but this was difficult to determine.

Treatment.—The inunctions were begun at once, and by the end of two months the child was apparently perfectly healthy. It soon passed from observation and I have never seen it since.

In these cases we have every one of the varieties which I have seen described. In the first we have a well-developed child with flaccidity of the upper extremities, slight thickening of the cartilage, no pain on motion or tenderness on pressure, no attempt to move even so much as the fingers and no response to tickling the palms. In this case the immobility can hardly be ascribed to pain, but, as it appears to me, the general appearance is strongly suggestive of nerve involvement.

In the second case we have a poorly developed child, flaccidity of upper extremities as in Case 1, separation of the epiphysis, no attempts to move even fingers, no pain or tenderness on handling or motion. Here the immobility might be ascribed to separation of the epiphysis, but this does not account for the lack of motion in the fingers and the failure to respond to irritation of the palm, and again we have a strong suspicion of involvement of the nerves.

As noted, the legs presented a different picture. They were rotated outward. There was every evidence of pain on pressure or the slightest motion. Muscles were contracted and painful and general spasticity was present, yet the toes contracted when the soles were tickled. In this case we have the suggestion that immobility was due to pain either from myositis or epiphysitis, the muscles contracting in an effort to immobilize the joint, rather than from nerve involvement.

The treatment of the condition should be directed to the counteraction of the specific poison by means of inunctions. Sutherland suggests splints and local applications of mercurial ointment, which he believes to be of special value since he has seen pseudoparalysis develop while child was taking general syphilitic treatment.

I have attempted to write nothing new, but merely to call attention to the importance of the recognition of this condition and its diagnosis, and in the light of what we have before us it seems to me that further investigation of this very interesting condition would be profitable.

NODULAR OPACITY OF THE CORNEA

WITH SPECIAL REFERENCE TO ITS ETIOLOGY*

JOHN GREEN, Jr., A.B., M.D.
Ophthalmic Surgeon to the Social Service Hospital
ST. LOUIS

The ophthalmic literature of the last thirty years contains occasional references to a rare ocular disease characterized by the presence of fairly well-defined opacities situated in the central portion of the cornea. These opacities vary in size and contour and lie in the otherwise relatively clear tissue. The condition was not recognized as a distinct malady until Groenouw, in 1890,[1] and again in 1898,[2] made it the subject of clinical investigation and pathologic study. Since then a number of observers have dealt with the condition and a few have subjected the diseased tissue to histologic examination.

Groenouw states that nodular opacity of the cornea begins with slight inflammatory signs, which are often so insignificant as to escape the notice of the patient. It attacks both eyes and is distinguished by the appearance of numerous, small, roundish or irregular, gray discrete opacities in the otherwise relatively clear corneal tissue. The larger masses, which are situated principally in the superficial layers of the center of the cornea, attain a diameter of 0.25 mm. The overlying epithelium is frequently elevated, but not vesicular. Under high magnification the corneal surface between the masses is seen to be very faintly cloudy.

Our knowledge of the condition was considerably extended by Fuchs[3] on the basis of eight carefully observed cases. He found that the trouble sh a special predilection for young men; (11 males, ale, in the 12
cases in the literature up to 1902). characte

The extreme this disease is a
fact that Fuchs the conditic
times in a materi upwards of
cases. At present erature
22 authentic cases. (Groenouw 2, Fuchs 8, Holmes-Spicer 2, Chevallereau 1, Krukow 3, Gillius 2, Wehrli 2, Treacher Collins 1, and Paderstein 1.)

SYMPTOMATOLOGY

The disease is ushered in by moderate photophobia, epiphora, and occasionally a foreign body sensation. There is no true pain but only a sense of ocular discomfort. These signs are accompanied by diminution of visual acuity. Throughout the long course of the disease there is a conspicuous absence of active inflammatory appearances, although now and again a transient redness, accompanied by photophobia, will manifest itself. The course of the disease is essentially chronic.

In view of its progressive character and rebelliousness to all therapeutic methods, the disease is one that deserves the careful attention of ophthalmologists. The final visual outcome varies from tolerably good vision to finger-counting.

DIFFERENTIAL DIAGNOSIS

Nodular opacity of the cornea is to be distinguished from a number of more or less similar conditions. Fuchs calls attention to some distinguishing features between this disease and superficial punctate keratitis. In nodular opacity the spots are compact and homogeneous. There are no inflammatory appearances and the clinical aspect may remain unchanged for years. In superficial punctate keratitis, on the contrary, the spots are made up of an agglomeration of the very finest dots. Inflammatory appearances are invariably present and the condition undergoes rapid changes. Von Reuss,[4] under the name of "keratitis maculosa," describes a disease consisting of disc-like masses surrounded by a ring occupying for the most part the periphery of the cornea, but also at times the center. Nummular keratitis (Stellwag[5]) consists of very large masses of a saturated yellowish tint lying mostly in the periphery of the cornea and in the superficial layers. Both types, in contradiction to nodular keratitis, offer a good prognosis. Grill-like keratitis is a condition which, in respect to its course, its situation in the center of the cornea and the elevation of the epithelium over the lesions, presents many points of similarity. It is distinguished by the very definite mesh-work or interlacing arrangement of the linear opacities. Fuchs suggests that nodular opacity bears some resemblance to certain cases of old eczematous keratitis in which a thinning of the epithelium over one or more of the denser opacities produces a bluish-white prominence of the corneal surface. According to Morax[6] the disease may be confused with syphilitic nodular keratitis, in
ich the infiltrations, either solitary or in groups, are
grayish-yellow color. They develop slowly, last for
l month nd finally disappear, leaving only in-
ant de or superficial opacities in the cornea.

fact that the periphery of the cornea is involved and that the corneal surface is smooth and shiny.

HISTOLOGY OF THE AFFECTION

Fragments of the diseased tissue have been studied histologically by Groenouw,[2] Fuchs,[3] Chevallereau,[8] and Wehrli.[9] The only report based on the examination of the entire globe is the recent one of Paderstein.[10] Groenouw's specimens showed a foreign substance lying partly isolated and partly in large masses in the substantia propria of the cornea. Just beneath the epithelium the material appeared finely granular and exhibited a certain parallel or interlacing arrangement. It had the appearance of a foreign substance interposed between the corneal fibers. Adjacent to the deposits the corneal corpuscles were deformed and greatly increased in numbers. There was no change in the epithelium or Bowman's membrane. From the chemical reactions of the amorphous substance Groenouw was led to believe that it was of a hyaline nature. The presence of this substance he explains on two grounds: either it was a transformation product of the corneal substance or a foreign mass deposited in it. He admits the possibility of a combination of the two processes.

In Case 6 of Fuchs' series, a fragment of the corneal tissue from the pupillary area, 4 mm. in diameter and 0.25 mm. in thickness, was excised with a corneal trephine. The pathologic appearances, which were confined to the superficial layers of the cornea, were as follows: The epithelium covering the nodules was greatly thinned and the cells flattened. The more superficial corneal lamellæ were swollen and, at sites corresponding to the nodules, were separated. Between the superficial and deeper layers appeared a deposit of amorphous substance, which was not present beneath the nodules. The substance contained isolated corneal fibers and wandering cells. Bowman's membrane could not be seen. When stained with thionin those layers beneath the amorphous deposit took a violet color, instead of the usual blue-green of normal corneal tissue. There appeared then four alterations from the normal: (1) swollen appearance of the upper corneal layers throughout; (2) fibrillation of these layers in limited areas; (3) a deposit of amorphous substance; (4) a change of the underlying lamellæ. Fuchs assumed a metabolic change in the superficial layers leading to the formation of a pathologic fluid. This fluid brought about a swelling of the superficial layers, and, accumulating between the lamellæ, separated and finally destroyed them. He was unable to reconcile the anatomic findings in his case with those of Groenouw and others and was forced to adopt the hypothesis that etiologically and anatomically different processes gave rise to clinically indistinguishable corneal conditions. He concludes that the disease is due to a general, as yet unknown, nutritional disturbance of which the sole expression so far observed is the eye disease.

Chevallereau[8] found crystals of sodium urate lying between the superficial corneal layers.

Paderstein[10] reports the only histologic examination of the entire globe in a case of nodular opacity of the cornea. He found thinning of the epithelium and altered relations of the round and cylindrical cells. The space of the missing cells was filled with a homogeneous hyaline substance, which also appeared on or slightly separated from Bowman's membrane. In places the nodules appeared to be made up of layers of hyaline "like the flakes of an onion." Elsewhere the hyaline assumed a fibrous appearance. Bowman's membrane varied in thickness and was pressed together by the overlying nodules. In places a sharp differentiation between the hyaline and Bowman's membrane was not possible. The hyaline lay also on the basal epithelial cells. These, and to some extent other epithelial cells, had separated from neighboring cells. Their nuclei were partly normal, partly degenerated, and vacuolated. There were no pathologic changes in the corneal parenchyma. Paderstein believes that the basal epithelial cell layer was the primary seat of the affection, and outlines the series of pathologic events as follows: A degeneration of the epithelial cells resulted in the formation of hyaline. The nodules and projections were formed by agglomeration of degenerated cells. Between the cell groups, which had passed through a complete transformation, were scattered some in which the degenerative process was not completed. Thus are to be explained the cells and cell remains in the spaces between the layers of the deposit.

From the above descriptions it can readily be seen that the histologic findings, though presenting some points of similarity, are widely at variance in others. Entirely unrelated to any appearances described by other observers are the findings of Wehrli.[9] This author encountered the disease in two brothers, one of whom had passed through an attack of tuberculous peritonitis. He excised some of the nodules and introduced them into the anterior chamber of a rabbit. There was a sharp reaction with the appearance of a transient yellowish exudate around the fragments, but nine months later the rabbit's eyes were apparently normal. The histologic findings included enlargement of a portion of the fixed corneal cells and increase and regressive processes in a number of the same. The large cells were arranged in groups and bore a striking resemblance to the histologic disposal of the cell nests of epithelioid nodules of tuberculous or syphilitic granulomata. Furthermore, there were found large cells with several nuclei, similar to giant cells. The connective tissue fibers had a sort of cicatricial character. Those next to the so-called tubercles were granular and homogeneous. An amorphous substance deposited in the superficial layers was regarded by Wehrli as necrotic débris from the destruction of tuberculous nodules. By the Ziehl-Nielson method Wehrli found, after long search, two apparently segmented, slightly curved bacilli, coloring faintly red, which he believed to be tubercle bacilli.

In view of the extraordinary rarity of the affection, and also of Wehrli's dictum that every observed case deserves recording, I venture to present the following typical example of nodular opacity of the cornea:

REPORT OF CASE

General History.—R. V. O., aged 27, male, married, came under observation Oct. 30, 1908. His mother died of tuberculosis of the lungs at the age of 40, the patient being 10 years old at the time. A maternal aunt also died of the same disease. As a young boy the patient was perfectly healthy. At the age of 9, he fell out of a swing and landed on his back. The following day a "ridge" appeared around the waist, not accompanied by pain. This remained and two or three weeks later a swelling appeared on the left hip, which was lanced and discharged pus. Other swellings of a similar nature appeared to the right of the sacrum near the coccyx and over the left gluteal muscles. All these swellings were lanced and discharged pus for several years, finally healing when the

NODULAR OPACITY OF THE CORNEA

WITH SPECIAL REFERENCE TO ITS ETIOLOGY[*]

JOHN GREEN, Jr., A.B., M.D.
Ophthalmic Surgeon to the Social Service Hospital
ST. LOUIS

The ophthalmic literature of the last thirty years contains occasional references to a rare ocular disease characterized by the presence of fairly well-defined opacities situated in the central portion of the cornea. These opacities vary in size and contour and lie in the otherwise relatively clear tissue. The condition was not recognized as a distinct malady until Groenouw, in 1890,[1] and again in 1898,[2] made it the subject of clinical investigation and pathologic study. Since then a number of observers have dealt with the condition and a few have subjected the diseased tissue to histologic examination.

Groenouw states that nodular opacity of the cornea begins with slight inflammatory signs, which are often so insignificant as to escape the notice of the patient. It attacks both eyes and is distinguished by the appearance of numerous, small, roundish or irregular, gray discrete opacities in the otherwise relatively clear corneal tissue. The larger masses, which are situated principally in the superficial layers of the center of the cornea, attain a diameter of 0.25 mm. The overlying epithelium is frequently elevated, but not vesicular. Under high magnification the corneal surface between the masses is seen to be very faintly cloudy.

Our knowledge of the condition was considerably extended by Fuchs[3] on the basis of eight carefully observed cases. He found that the trouble showed a special predilection for young men; (11 males, 1 female, in the 12 cases in the literature up to 1902). It was characterized by: (1) considerable roughness of the corneal surface; (2) gray, roundish or irregular opacities situated in the pupillary area and projecting above the corneal surface; (in general the larger irregular masses were surrounded by smaller roundish ones, the latter exhibiting a circular arrangement); (3) a faint diffuse opacity of the rest of the cornea which, under high magnification, resolved itself into very tiny punctations. The configuration of the opacities slowly altered in the course of years.

The extreme rarity of this disease is attested by the fact that Fuchs encountered the condition only eight times in a material comprising upwards of 250,000 eye cases. At present writing the literature contains only 22 authentic cases. (Groenouw 2, Fuchs 8, Holmes-Spicer 2, Chevallereau 1, Krukow 3, Gillius 2, Wehrli 2, Treacher Collins 1, and Paderstein 1.)

SYMPTOMATOLOGY

The disease is ushered in by moderate photophobia, epiphora, and occasionally a foreign body sensation. There is no true pain but only a sense of ocular discomfort. These signs are accompanied by diminution of visual acuity. Throughout the long course of the disease there is a conspicuous absence of active inflammatory appearances, although now and again a transient redness, accompanied by photophobia, will manifest itself. The course of the disease is essentially chronic.

In view of its progressive character and rebelliousness to all therapeutic methods, the disease is one that deserves the careful attention of ophthalmologists. The final visual outcome varies from tolerably good vision to finger-counting.

DIFFERENTIAL DIAGNOSIS

Nodular opacity of the cornea is to be distinguished from a number of more or less similar conditions. Fuchs calls attention to some distinguishing features between this disease and superficial punctate keratitis. In nodular opacity the spots are compact and homogeneous. There are no inflammatory appearances and the clinical aspect may remain unchanged for years. In superficial punctate keratitis, on the contrary, the spots are made up of an agglomeration of the very finest dots. Inflammatory appearances are invariably present and the condition undergoes rapid changes. Von Reuss,[4] under the name of "keratitis maculosa," describes a disease consisting of disc-like masses surrounded by a ring occupying for the most part the periphery of the cornea, but also at times the center. Nummular keratitis (Stellwag[5]) consists of very large masses of a saturated yellowish tint lying mostly in the periphery of the cornea and in the superficial layers. Both types, in contradiction to nodular keratitis, offer a good prognosis. Grill-like keratitis is a condition which, in respect to its course, its situation in the center of the cornea and the elevation of the epithelium over the lesions, presents many points of similarity. It is distinguished by the very definite mesh-work or interlacing arrangement of the linear opacities. Fuchs suggests that nodular opacity bears some resemblance to certain cases of old eczematous keratitis in which a thinning of the epithelium over one or more of the denser opacities produces a bluish-white prominence of the corneal surface. According to Morax[6] the disease may be confused with syphilitic nodular keratitis, in which the infiltrations, either solitary or in groups, are of a grayish-yellow color. They develop slowly, last for several months and finally disappear, leaving only insignificant deep or superficial opacities in the cornea. Under the title "Spotted Family Degeneration of the Cornea," Fehr[7] describes a condition observed by him in two sisters and a brother. Each cornea showed a milky opacity in which scattered dots of greater saturation were distinguishable. Under magnification the diffuse opacity resolved itself into tiny punctations and the more saturated masses were seen to be due to the crowding together of the individual punctations. This condition is distinguished from nodular opacity by the fact that the periphery of the cornea is involved and that the corneal surface is smooth and shiny.

patient was about 17 years old, leaving large deep scars. For a time the left knee was flexed and the patient had to use a crutch. There was no pain in the joints at any time. At the age of 16 the patient passed several kidney stones, preceded by severe pains in the lumbar region. Six years before he came under my observation he had a severe attack of measles and gonorrhea three years later—mild attack, no complications. He positively denied syphilis. For the past ten years he had been exceedingly healthy, though troubled with a winter cough. His average weight was 135, maximum 150 (present weight.)

General Examination.—I am indebted to Dr. L. M. Warfield for the general physical examination. This showed a puckered scar on the left groin three inches in length, one on right groin, one large deep scar opposite the left trochanter, one on each side of the upper part of the sacrum, small one to the right of the coccyx, one puckered scar below the edge of the gluteus maximus. At the lowest lumbar spine the bones were thickened; there was no pain, no limitation of motion, slight limitation of adduction. The lungs and heart were normal. The scars were typical tuberculous cutaneous scars. There was no evidence of syphilis.

Ocular History.—About three years before the time of examination the patient noticed a sandy or gritty sensation accompanied by slight epiphora and photophobia and found that his sight was growing dim. There was no noticeable redness and at no time any true inflammatory signs. A year later he consulted an oculist who used various local medicaments and gave mercury by the mouth. Vision grew slowly worse, though there were transient periods of slight improvement.

Ocular Examination.—There was no conjunctival or ciliary congestion in either eye. R. V. 18/150. L. V. 18/96. Examination with the binocular loupe disclosed five or six, very irregular, rather ill-defined grayish masses occupying the center of the right cornea. These masses were, in general, grouped in the form of an ellipse, the center of which was occupied by a nebulous area. The left cornea presented much the same appearance, the opacities being of irregular shape, rather more sharply defined than in the right eye and arranged in the form of a flattened ellipse. The center of the ellipse was rather clearer than in the right eye. With the aid of the Zeiss corneal microscope a very beautiful picture presented itself. In the right eye (Fig. 1), the irregular masses appeared fluffy, like cumulus clouds, with ill-defined margins, shading into relatively clear cornea. The masses could not be resolved into separate dots, but appeared quite homogeneous. Where two separate masses lay near together there was a decided tendency for them to merge or coalesce. The tissue occupying the center of the ellipse was distinctly nebulous. Here and there, the epithelium over the nodules appeared elevated, so that it formed a tiny facet and reflected a laterally projected pencil of light. Outside the involved central area the cornea was very faintly nebulous and this cloudiness extended right up to the corneal margin. The lesions were situated in the superficial layers, but here and there appeared to dip well back into the corneal stroma. The iris showed no alteration. In the left eye (Fig. 2) the masses were somewhat better defined than in the right, i.e., the line of demarcation between the individual nodules and the contiguous tissue was better defined. The nodules themselves were not as fluffy as in the right eye but appeared homogeneous. The space between the masses was rather less nebulous than the corresponding space in the right eye. The epithelium over the nodules was elevated and irregular. The periphery of the cornea contained an extremely delicate gray opacity which resolved itself into the finest of dots. The fundus of each eye was normal. Tension normal; pupils equal; pupillary reaction normal both to light and convergence. The general appearance of the cornea is well illustrated by the accompanying pictures. These were drawn, however, some three months after treatment was begun and do not show the distinct internodular opacity in the left eye visible at the first examination. The history of the case, together with the quite typical appearance, left no doubt as to the diagnosis of nodular opacity of the cornea.

Treatment and Course of Disease.—Bearing in mind the clear tuberculous family history, and the unquestioned tuberculous nature of the old cutaneous ulcerations, I was impressed with the possibility that the eye lesion might be of the same nature. It was, therefore, decided to try the effect of a diagnostic injection of tuberculin.

October 31: At 3 p. m., 3 mg. of old tuberculin were injected into the upper left arm. The following day, November 1, 11 a. m., temperature was 98.4 F. There was very slight redness and soreness at the point of inoculation, with some palpable thickening. At 8 p. m., temperature 99 F.

November 2: Arm quite sore; 3 mg. old tuberculin were injected in the right arm.

November 3: Both conjunctivæ were injected and there was some ciliary congestion. Patient complained of much discomfort, increased photophobia and stickiness of the lids. On examination with the corneal microscope the nodules in the right eye especially were denser and more fluffy than at the first examination. R. E. V. 18/192. L. E. V. 18/96.

November 5: Both arms were found to be indurated at the site of the injections. Three mg. old tuberculin were given.

November 6: Patient stated that he had had a bad night; severe headache; now felt quite sick. At 10 a. m., temperature 99.4 F. Large induration at point of inoculation. At 4 p. m., temperature 100.6 F. R. V. 18/75. L. V. 18/38. The corneal microscope now showed a distinct thinning of the cloudy nodules in the right cornea and a diminution in the internodular opacity. The left eye showed a very distinct diminution in the internodular opacity but no noticeable change in the nodules themselves. The patient expressed his surprise at the sudden improvement in vision.

Diagnostic tuberculin injections were suspended and the patient was not seen again until November 12, on which date therapeutic doses were instituted, beginning with 0.01 mg. of old tuberculin. At intervals of three or four days old tuberculin was injected, increasing 0.01 mg. at each dose.

December 3: The dosage was 0.05 mg. and, for the first time, evoked some soreness at the point of injection.

The dosage was reduced to 0.02 and gradually increased at intervals of a week to 0.03, 0.04 and finally 0.055 mg. when treatment was suspended. The therapeutic injections between Nov. 12, 1908, and Jan. 13, 1909, numbered fifteen. At each visit the corneæ were very carefully examined with the corneal microscope and it was possible to note a gradual diminution in the internodular opacity, especially of the left eye.

On March 1, 1909, the masses were decidedly less dense and in the right eye were more sharply delimited than at first. This change in the appearance was accompanied by gradual improvement in vision so that at this date R. V. 18/60. L. V. 18/30. The patient was much gratified with the improvement in vision as he had about made up his mind that he was going blind. Local treatment has been confined to bland collyria and (for a week only) dionin 3 per cent solution. This was suspended, as it provoked a good deal of discomfort. I was anxious to secure a fragment of the cornea for histologic examination but the patient declined any operative interference whatsoever.

I have later learned that the patient's sister, residing in Kentucky, has had defective vision for a number of years. To a letter requesting particulars of the malady she replied that she had been troubled with her eyes for five years. There had never been any inflammation, the main difficulty being defective vision. She had tried several pairs of glasses but found none that helped. "Over the sight of the eyes are several white specks about the size of a pin-head."

We have, then, in a patient with a very clear family history of tuberculosis, who himself had passed through a severe cutaneous tuberculous affection, a typical nodular opacity of both corneæ. The absence of any etiologic factor aside from tuberculosis which might conceivably have given rise to such a process, the general and local reaction to the diagnostic tuberculin test, the lessening of the density of the nodules, the clearing of the internodular opacities and notable improvement in vision under tuberculin therapy, lead me to the belief that this case is an attenuated tuberculosis of the cornea.

Writers subsequent to Wehrli have been disposed to ignore his findings and conclusions, seeming tacitly to assume that because they did not coincide in any particular with those of other observers they must be faulty. In the light of my own case such a point of view seems to me not justified.

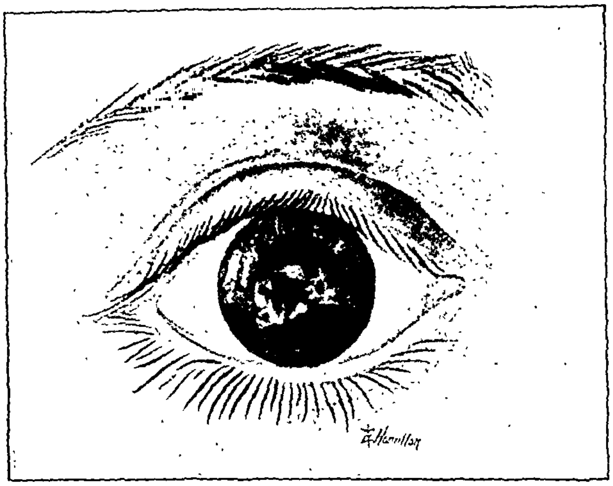

Fig. 1—Nodular opacity of the cornea, right eye.

In the present state of our knowledge with regard to this peculiar affection, we must adopt the view that cases of nodular opacity of the cornea, clinically indistinguishable, may differ with respect to their etiology and histology. It seems proper to regard the cases of Groenouw and Fuchs as instances of a general nutritional disturbance of which the sole expression is the corneal lesion. On the other hand, the histologic findings of Wehrli and the diagnostic and therapeutic efficiency of tuberculin in the case here reported seem to indicate that some of these cases may be, as Wehrli has pointed out, examples of attenuated tuberculosis of the cornea.

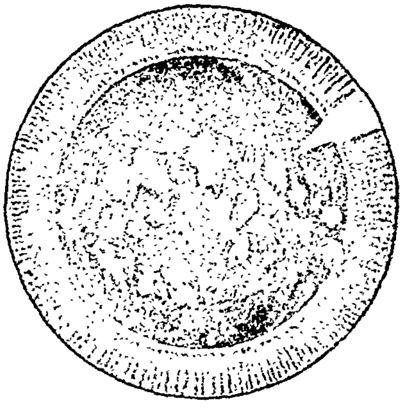
ABSTRACT OF DISCUSSION

Dr. Edward A. Shumway, Philadelphia: Any communication which helps to determine the etiology, and to suggest the treatment, of an obscure condition must be considered of great importance. Reports of cases of nodular keratitis are becoming more frequent in ophthalmic literature, especially in Great Britain. Hancock (*Trans. Ophth. Soc. United Kingdom*, 1905, p. 64) reported two in a mother and son, and Dawnay (*ibid.*) reported two in sisters in 1905. Leslie Buchanan (*Ophthalmoscope*, December, 1907) gave the histories of two brothers in whom the disease was apparently arrested, and the vision much improved by iridectomy, and three cases in one family were seen by A. McNab (*Trans. Ophth. Soc. United Kingdom*, 1907, p. 81) and described in the same year. In December, 1908, Folker (*Ophth. Rev.*, xxvii, p. 385) reported seven cases in three generations of one family before the Ophthalmic Society of the United Kingdom, and in the discussion McNab advanced the suggestion that a tuberculous diathesis might be the cause of the condition. Finally, a patient was shown by Zentmayer before the Ophthalmological Section of the College of Physicians, in Philadelphia, in February, 1909, in whom a general but no local reaction to tuberculin was obtained. So that even if we limit the case to the typical nodular form, with discrete opacities in the center of otherwise relatively clear corneæ, and with roughening of the surface, as a result of the elevations of the corneal epithelium, and exclude the cases of grill-like keratitis and family degeneration of the cornea, often considered to be of the same general type, the literature of the subject has greatly increased in recent years.

Most surgeons who have reported cases of nodular keratitis have assumed that some dyscrasia was at the bottom of the trouble, and that the opacities were due to degenerative changes, beginning either in the corneal epithelium or in the superficial corneal lamellæ. If it can be shown that in at least some of them tuberculosis is present, a notable advance will be made in treatment. The entire absence of inflammatory reaction and the absence of cellular infiltration in the majority of cases which have been examined histologically, except as in Paderstein's case, as a secondary condition, have probably prevented the authors from taking tuberculosis into consideration, as the ordinary forms of tuberculous keratitis are attended with stubborn and well-pronounced signs of inflammation. Moreover, the occurrence of a general reaction to tuberculin is not proof positive that a local condition in the cornea is tuberculous, although of sufficient importance to warrant antituberculous treatment. It is imperative for us to examine each new case minutely for the presence of a tuberculous history, or a focus of tuberculosis elsewhere in the body, and especially to try the subcutaneous test with tuberculin. In the presence of such a factor, the treatment with tuberculin injections, commencing with small doses, as Dr. Green has done, should be adopted. If such treatment fails of success, the results obtained by Buchanan by iridectomy should be remembered, in our efforts to check what has been considered a hopelessly progressive form of blindness.



Drawing showing corneal lesions in left eye in case mentioned by Dr. Zentmayer in the discussion. Right eye practically the same.

Dr. William Zentmayer, Philadelphia: I hesitate to report a case in discussion, but I desire to record the condition present in my case [see illustration above] and to report the pathologic findings. The epithelium varies from 20 to 30 cell layers to 2 or 3 cell layers deep. There is a general cloudy patient was about 17 years old, leaving large deep scars. For a time the left knee was flexed and the patient had to use a crutch. There was no pain in the joints at any time. At the age of 16 the patient passed several kidney stones, preceded by severe pains in the lumbar region. Six years before he came under my observation he had a severe attack of measles and gonorrhea three years later—mild attack, no complications. He positively denied syphilis. For the past ten years he had been exceedingly healthy, though troubled with a winter cough. His average weight was 135, maximum 150 (present weight.)

General Examination.—I am indebted to Dr. L. M. Warfield for the general physical examination. This showed a puckered scar on the left groin three inches in length, one on right groin, one large deep scar opposite the left trochanter, one on each side of the upper part of the sacrum, small one to the right of the coccyx, one puckered scar below the edge of the gluteus maximus. At the lowest lumbar spine the bones were thickened; there was no pain, no limitation of motion, slight limitation of adduction. The lungs and heart were normal. The scars were typical tuberculous cutaneous scars. There was no evidence of syphilis.

Ocular History.—About three years before the time of examination the patient noticed a sandy or gritty sensation accompanied by slight epiphora and photophobia and found that his sight was growing dim. There was no noticeable redness and at no time any true inflammatory signs. A year later he consulted an oculist who used various local medicaments and gave mercury by the mouth. Vision grew slowly worse, though there were transient periods of slight improvement.

Ocular Examination.—There was no conjunctival or ciliary congestion in either eye. R. V. 18/150. L. V. 18/96. Examination with the binocular loupe disclosed five or six, very irregular, rather ill-defined grayish masses occupying the center of the right cornea. These masses were, in general, grouped in the form of an ellipse, the center of which was occupied by a nebulous area. The left cornea presented much the same appearance, the opacities being of irregular shape, rather more sharply defined than in the right eye and arranged in the form of a flattened ellipse. The center of the ellipse was rather clearer than in the right eye. With the aid of the Zeiss corneal microscope a very beautiful picture presented itself. In the right eye (Fig. 1), the irregular masses appeared fluffy, like cumulus clouds, with ill-defined margins, shading into relatively clear cornea. The masses could not be resolved into separate dots, but appeared quite homogeneous. Where two separate masses lay near together there was a decided tendency for them to merge or coalesce. The tissue occupying the center of the ellipse was distinctly nebulous. Here and there, the epithelium over the nodules appeared elevated, so that it formed a tiny facet and reflected a laterally projected pencil of light. Outside the involved central area the cornea was very faintly nebulous and this cloudiness extended right up to the corneal margin. The lesions were situated in the superficial layers, but here and there appeared to dip well back into the corneal stroma. The iris showed no alteration. In the left eye (Fig. 2) the masses were somewhat better defined than in the right, i.e., the line of demarcation between the individual nodules and the contiguous tissue was better defined. The nodules themselves were not as fluffy as in the right eye but appeared homogeneous. The space between the masses was rather less nebulous than the corresponding space in the right eye. The epithelium over the nodules was elevated and irregular. The periphery of the cornea contained an extremely delicate gray opacity which resolved itself into the finest of dots. The fundus of each eye was normal. Tension normal; pupils equal; pupillary reaction normal both to light and convergence. The general appearance of the cornea is well illustrated by the accompanying pictures. These were drawn, however, some three months after treatment was begun and do not show the distinct internodular opacity in the left eye visible at the first examination. The history of the case, together with the quite typical appearance, left no doubt as to the diagnosis of nodular opacity of the cornea.

Treatment and Course of Disease.—Bearing in mind the clear tuberculous family history, and the unquestioned tuberculous nature of the old cutaneous ulcerations, I was impressed with the possibility that the eye lesion might be of the same nature. It was, therefore, decided to try the effect of a diagnostic injection of tuberculin.

October 31: At 3 p. m., 3 mg. of old tuberculin were injected into the upper left arm. The following day, November 1, 11 a. m., temperature was 98.4 F. There was very slight redness and soreness at the point of inoculation, with some palpable thickening. At 8 p. m., temperature 99 F.

November 2: Arm quite sore; 3 mg. old tuberculin were injected in the right arm.

November 3: Both conjunctivæ were injected and there was some ciliary congestion. Patient complained of much discomfort, increased photophobia and stickiness of the lids. On examination with the corneal microscope the nodules in the right eye especially were denser and more fluffy than at the first examination. R. E. V. 18/192. L. E. V. 18/96.

November 5: Both arms were found to be indurated at the site of the injections. Three mg. old tuberculin were given.

November 6: Patient stated that he had had a bad night; severe headache; now felt quite sick. At 10 a. m., temperature 99.4 F. Large induration at point of inoculation. At 4 p. m., temperature 100.6 F. R. V. 18/75. L. V. 18/38. The corneal microscope now showed a distinct thinning of the cloudy nodules in the right cornea and a diminution in the internodular opacity. The left eye showed a very distinct diminution in the internodular opacity but no noticeable change in the nodules themselves. The patient expressed his surprise at the sudden improvement in vision.

Diagnostic tuberculin injections were suspended and the patient was not seen again until November 12, on which date therapeutic doses were instituted, beginning with 0.01 mg. of old tuberculin. At intervals of three or four days old tuberculin was injected, increasing 0.01 mg. at each dose.

December 3: The dosage was 0.05 mg. and, for the first time, evoked some soreness at the point of injection.

The dosage was reduced to 0.02 and gradually increased at intervals of a week to 0.03, 0.04 and finally 0.055 mg. when treatment was suspended. The therapeutic injections between Nov. 12, 1908, and Jan. 13, 1909, numbered fifteen. At each visit the corneæ were very carefully examined with the corneal microscope and it was possible to note a gradual diminution in the internodular opacity, especially of the left eye.

On March 1, 1909, the masses were decidedly less dense and in the right eye were more sharply delimited than at first. This change in the appearance was accompanied by gradual improvement in vision so that at this date R. V. 18/60. L. V. 18/30. The patient was much gratified with the improvement in vision as he had about made up his mind that he was going blind. Local treatment has been confined to bland collyria and (for a week only) dionin 3 per cent solution. This was suspended, as it provoked a good deal of discomfort. I was anxious to secure a fragment of the cornea for histologic examination but the patient declined any operative interference whatsoever.

I have later learned that the patient's sister, residing in Kentucky, has had defective vision for a number of years. To a letter requesting particulars of the malady she replied that she had been troubled with her eyes for five years. There had never been any inflammation, the main difficulty being defective vision. She had tried several pairs of glasses but found none that helped. "Over the sight of the eyes are several white specks about the size of a pin-head."

We have, then, in a patient with a very clear family history of tuberculosis, who himself had passed through a severe cutaneous tuberculous affection, a typical nodular opacity of both corneæ. The absence of any etiologic factor aside from tuberculosis which might conceivably have given rise to such a process, the general and local reaction to the diagnostic tuberculin test, the lessening of the density of the nodules, the clearing of the internodular opacities and notable improvement in vision under tuberculin therapy, lead me to the belief that this case is an attenuated tuberculosis of the cornea.

Writers subsequent to Wehrli have been disposed to ignore his findings and conclusions, seeming tacitly to assume that because they did not coincide in any particular with those of other observers they must be faulty. In the light of my own case such a point of view seems to me not justified.

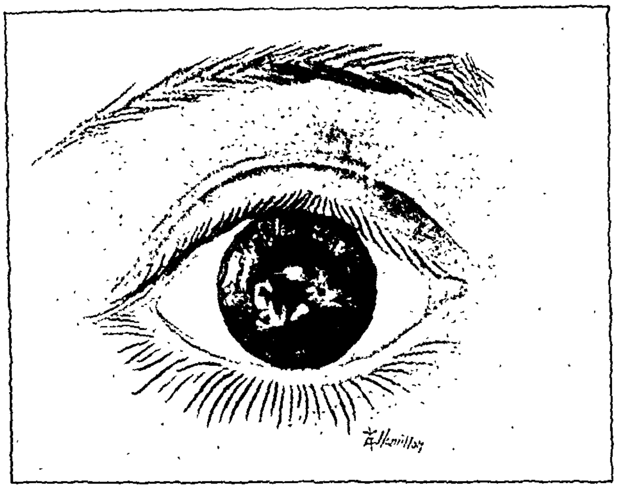


Fig. 1—Nodular opacity of the cornea, right eye.

In the present state of our knowledge with regard to this peculiar affection, we must adopt the view that cases of nodular opacity of the cornea, clinically indistinguishable, may differ with respect to their etiology and histology. It seems proper to regard the cases of Groenouw and Fuchs as instances of a general nutritional disturbance of which the sole expression is the corneal lesion. On the other hand, the histologic findings of Wehrli and the diagnostic and therapeutic efficiency of tuberculin in the case here reported seem to indicate that some of these cases may be, as Wehrli has pointed out, examples of attenuated tuberculosis of the cornea.

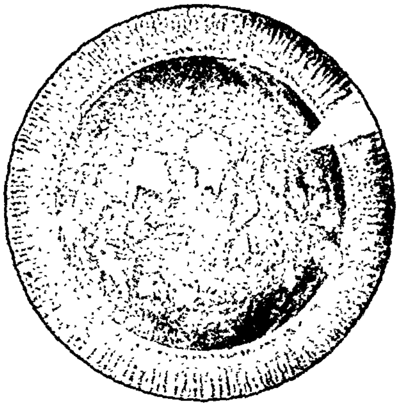
ABSTRACT OF DISCUSSION

Dr. Edward A. Shumway, Philadelphia: Any communication which helps to determine the etiology, and to suggest the treatment, of an obscure condition must be considered of great importance. Reports of cases of nodular keratitis are becoming more frequent in ophthalmic literature, especially in Great Britain. Hancock (*Trans. Ophth. Soc. United Kingdom*, 1905, p. 64) reported two in a mother and son, and Dawnay (*ibid.*) reported two in sisters in 1905. Leslie Buchanan (*Ophthalmoscope*, December, 1907) gave the histories of two brothers in whom the disease was apparently arrested, and the vision much improved by iridectomy, and three cases in one family were seen by A. McNab (*Trans. Ophth. Soc. United Kingdom*, 1907, p. 81) and described in the same year. In December, 1908, Folker (*Ophth. Rev.*, xxvii, p. 385) reported seven cases in three generations of one family before the Ophthalmic Society of the United Kingdom, and in the discussion McNab advanced the suggestion that a tuberculous diathesis might be the cause of the condition. Finally, a patient was shown by Zentmayer before the Ophthalmological Section of the College of Physicians, in Philadelphia, in February, 1909, in whom a general but no local reaction to tuberculin was obtained. So that even if we limit the case to the typical nodular form, with discrete opacities in the center of otherwise relatively clear corneæ, and with roughening of the surface, as a result of the elevations of the corneal epithelium, and exclude the cases of grill-like keratitis and family degeneration of the cornea, often considered to be of the same general type, the literature of the subject has greatly increased in recent years.

Most surgeons who have reported cases of nodular keratitis have assumed that some dyscrasia was at the bottom of the trouble, and that the opacities were due to degenerative changes, beginning either in the corneal epithelium or in the superficial corneal lamellæ. If it can be shown that in at least some of them tuberculosis is present, a notable advance will be made in treatment. The entire absence of inflammatory reaction and the absence of cellular infiltration in the majority of cases which have been examined histologically, except as in Paderstein's case, as a secondary condition, have probably prevented the authors from taking tuberculosis into consideration, as the ordinary forms of tuberculous keratitis are attended with stubborn and well-pronounced signs of inflammation. Moreover, the occurrence of a general reaction to tuberculin is not proof positive that a local condition in the cornea is tuberculous, although of sufficient importance to warrant antituberculous treatment. It is imperative for us to examine each new case minutely for the presence of a tuberculous history, or a focus of tuberculosis elsewhere in the body, and especially to try the subcutaneous test with tuberculin. In the presence of such a factor, the treatment with tuberculin injections, commencing with small doses, as Dr. Green has done, should be adopted. If such treatment fails of success, the results obtained by Buchanan by iridectomy should be remembered, in our efforts to check what has been considered a hopelessly progressive form of blindness.



Drawing showing corneal lesions in left eye in case mentioned by Dr. Zentmayer in the discussion. Right eye practically the same.

Dr. William Zentmayer, Philadelphia: I hesitate to report a case in discussion, but I desire to record the condition present in my case [see illustration above] and to report the pathologic findings. The epithelium varies from 20 to 30 cell layers to 2 or 3 cell layers deep. There is a general cloudy degeneration of all the epithelial cells tapering off at the extremity of the specimen into healthier cells which are probably a part of the surrounding clear cornea. The basal cells in one part of the section are approaching horny change, while in others they shade off into the partially homogeneous stroma. The cells of the stroma are degenerated, cloudy, the fibers in some parts have completely coalesced and in this region take a dull bluish stain like nuclear degeneration (hyaline degeneration). Bowman's membrane is absent in places; in others it is broken up and vacuolated. These findings correspond closely to those of Fuchs and Paderstein. The patient had a high-pitched apical note but there were no evidences of tuberculosis.

Dr. O. Wilkinson, Washington, D. C.: I reported a case several years ago in an elderly captain in the army aged about 70. He had been a hard drinker all his life, but there was no history of syphilis or tuberculosis. The opacity in the center of the cornea was highly nodular, while toward the periphery it was not so pronounced. The left eye, which was first affected, practically only had vision to count fingers. In the right eye, more recently involved, there was a typical central nodular opacity about the size of the ordinary pupil, but with dilated pupil he had fairly good vision. No histopathologic examination was made and he declined any form of operation. I suggested iridectomy for the benefit of vision, but that also was declined.

OSTEOMYELITIS OF THE LOWER JAW *

H. H. GERMAIN, M.D.
BOSTON

That true osteomyelitis of the mandible is an infrequent condition is generally conceded. Considering the opportunities offered for infection in this bone, it seems strange that the disease is not more commonly observed.

Many authors have remarked that the lower jaw is closely allied in structure to the long bones. This is partly true for the body, but not at all for the rami. The body differs from the long tubular bones in that teeth germs are present in childhood, while in the adult alveoli exist for the teeth. The rami resemble the flat bones, since their structure is denser and the marrow is of the spongy or diploetic variety. After the teeth have been lost and the alveolar process absorbed the body also assumes the character of the flat bone. In the jaw of the adult containing teeth the presence of large open marrow spaces together with the inferior dental canal favors the spreading of infection in the body of the bone. It appears, in fact, as has been emphasized by Dependorf,[1] that the canalis mandibularis possesses the same characteristics pathologically as the medullary cavity of the long bones. Infection travels along this canal with the greatest ease, while the surrounding medullary spaces act as reservoirs for pus. Hence in the body of the jaw the process is often a diffuse rapidly spreading disease. The above conditions do not obtain for the rami, and here we should expect the disease to be more localized. Kaleibe[2] and Dependorf,[1] who have investigated this condition, state that this is true and that small foci of suppuration are most often found in this portion of the bone in hematogenous infection.

ETIOLOGY

Having the above anatomic conditions in mind, our next task is to review the etiology of the disease. That the infectious agent finds entrance into the bony substance by way of the teeth goes without saying. Probably eight-tenths of all cases arise in this way. Infections from gangrenous pulps or from abscessed teeth are the most common (see Cases 1, 2 and 3). Impacted third molars also furnish a fair number of cases if one can judge from the number reported. Perthes[3] lays great stress on this latter cause. Pyorrhea alveolaris, noma and gangrenous stomatitis furnish occasional cases (Case 4).

Traumata without fracture may act as predisposing factors, as they produce extravasations and disturbances of circulation which furnish an opportunity for the carriers of infection to settle at the point of injury. Trauma resulting in fracture frequently furnishes a direct path for infection from the oral cavity or outer skin, since the majority of these fractures are compounds. Cases 5 and 6 are examples of fractures compound into the mouth, while Case 9 opened into the external auditory canal.

Excluding infection from the mouth or outer skin, the remaining cases are the result of hematogenous infection. These may follow acute infectious diseases, as scarlet fever and typhoid, or may accompany a septicemia from any cause. Hematogenous osteomyelitis is the only example of pure infection, usually of *Staphylococcus aureus* or streptococcus, which we have in the mandible. This refers, of course, to the condition before communication with the mouth is established. All others are necessarily mixed infection from contamination with mouth bacteria. It is probable that long exposure to cold and dampness is a predisposing factor to this disease; the same may be said of metallic poisons.

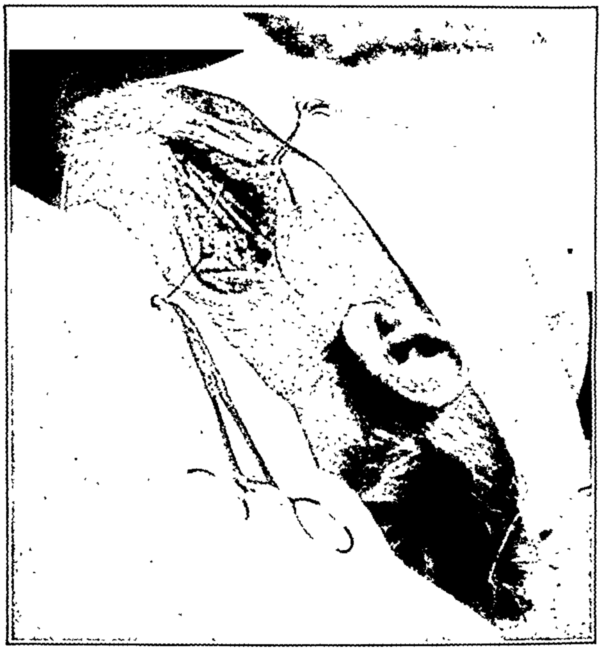


Fig. 1.—Completed operation, showing facial wall of lower jaw removed.

Previous to 1881 so-called idiopathic osteomyelitis was mentioned by Rosenbach[4] and Lannelongue,[5] but in that year Kaleibe pointed out and discussed in detail acute infectious osteomyelitis, recognizing the true nature of the disease.

SYMPTOMS AND COURSE

The sudden spontaneous appearance of gnawing pain is a phenomenon which is well known in all cases of osteomyelitis, regardless of situation. This is usually followed by more or less swelling of soft parts accompanied by fever, and after a time abscesses form and point into the mouth or externally through the cheek or outer skin. With the evacuation of pus temporary relief from pain is observed, but with the progress of the disease more abscesses form with recurrence of symptoms. If the process is diffuse the periosteum is stripped from the bone and the teeth loosen or are extracted to promote drainage of pus. Sooner or later part of the bone dies, and with the casting off of the sequestrum the process usually stops. Not infrequently a different course is seen; the suppuration and swelling are reduced and the disease becomes localized; the jaw thickens and the soft parts become dense and indurated. This localized form occurs most frequently in the ramus of the jaw in hematogenous cases, but it may occur in the body, provided good drainage is established.

---

The diffuse form is, as a rule, very acute, impairing the general health rapidily by septic absorption and also by the fact that the trismus which is present makes it impossible to masticate and swallow food. These patients can open the mouth a quarter of an inch or less, a condition which makes speech, deglutition and mastication difficult or impossible. It often happens that a large amount of pus is swallowed from discharging sinuses in the mouth. How much effect this has on the general condition is hard to estimate, but no one will deny that the circumstance is unfavorable to good digestion.

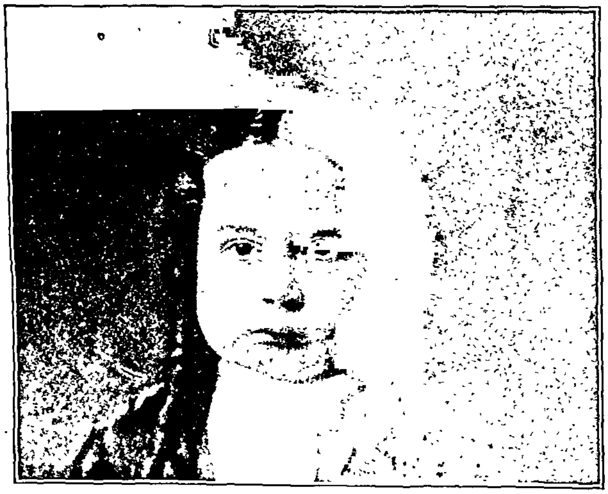

Fig. 2.—From photograph of Patient 3; note shortening of lower jaw.

Exactly what controls the size of the sequestrum in an untreated patient is impossible to say accurately. That a total necrosis does not frequently occur seems to be due to an inherent tendency which the marrow possesses to wall off the disease by the formation of dense bone from the endosteum. We have seen that anatomically and pathologically the long bones and the lower jaw are very similar, and it is to be noted that there is a third analogy, i. e., the uniformity in the conduct of the periosteum after loss of parts of the cortical bone. If diffuse necrosis occurs before complete development the longitudinal growth is, of course, much disturbed, but it is the rule that the diametrical growth will go on and new bone be formed provided the periosteum remains intact. The time required for the formation of a loose sequestrum varies in individual cases from twelve to twenty weeks, at the end of which time a fairly firm involucrum, or shell of periosteal bone, is formed. For some time the involucrum is soft and the muscles of the face and jaw produce a certain amount of deformity by shortening the newly formed mandible if the sequestrum includes the entire diameter of the jaw. As a result of this shortening there is malocclusion of greater or less degree as is seen in Case 3. As a rule it may be stated that the body and ramus will be reproduced, but the alveolar process will not be restored after destruction.

It has been noted that in practically all cases pus finds an outlet on the facial side of the mandible either in the mouth or externally. It is also true that part of the facial wall often becomes necrotic and is cast off as a sequestrum, while the labial side is rarely affected in cases of partial necrosis. The exact reason why the disease selects preferentially the facial side is not perfectly clear, but the large size of the marrow spaces below and to the outer side of the inferior dental canal offers the most likely explanation, since the line of least resistance is in this direction, i. e., toward the facial wall.

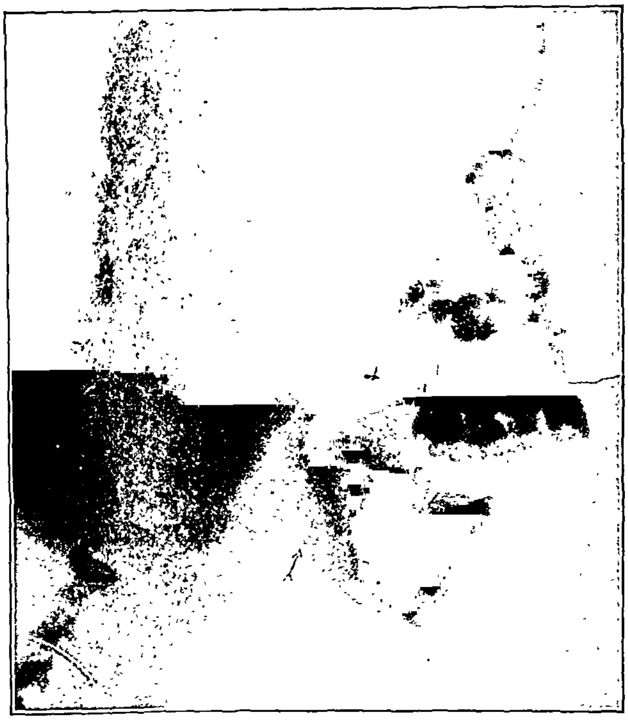

Fig. 3.—From x-ray of Patient 3; shortening of lower jaw apparent here also.

As has been observed, the symptoms in an acute case may subside, sinuses form and the disease take a subacute or chronic course. In this event it is usually found that there is a sequestrum present which must be removed. In the jaw there is also a possibility that there may be a dead tooth which can give the case the appearance of a chronic osteomyelitis. Cases of this kind are frequently seen and a number have been reported in which the external opening of the sinus was at a distance from the original cause in the jaw. The following is an example of one of these cases: Male, age 20, developed spontaneously a small abscess about the center of the anterior border of the right sternomastoid muscle. Abscess was drained, but a sinus persisted which resisted all treatment. Finally a dead second molar was extracted. Immediately blood appeared from the sinus and methyl blue dropped into the cavity left after extraction made its appearance at the external opening. Similar instances are reported by Perthes. In Case 9 of this series there was a sinus in the external auditory canal which on superficial examination resembled otitis media.

These teeth sinuses are particularly frequent in the region of the chin, where a dead incisor or cuspid may be the offending agent. Extraction of these dead teeth may be insufficient for cure, since a pocket of pus and granulations may be present at the apex of the root. Case 10 in the following series is an example.

DIAGNOSIS

Occasional difficulties in diagnosis will be experienced, but they are fortunately rare. Cases of malignant disease with secondary infection are stumbling-blocks which occur now and then. Syphilis and actinomycosis may, of course, confuse. Suppurating dentigerous cysts have been seen often enough to make one consider the possibility. Phosphorus necrosis is extremely rare at the present time. In all of the above conditions, except syphilis, the treatment is surgical and at operation there is rarely any difficulty as to the best course to pursue.

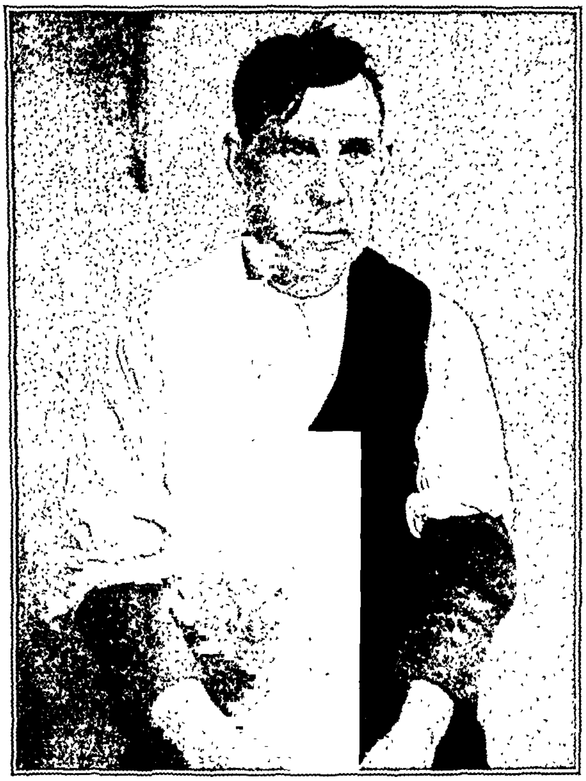

Fig. 4.—From photograph of Patient 6, front view.

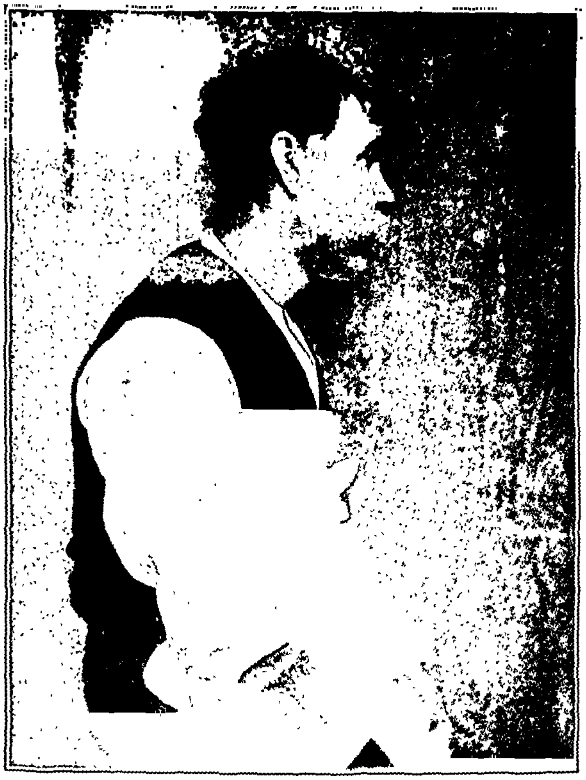

Fig. 5.—From photograph of Patient 6, side view.

The most valuable information may be obtained by the *x*-ray in cases in which the disease is localized, in which there is a definite sequestrum or in which fracture is a starting-point of the disease. In Cases 10 and 11 foci of suppuration were located with accuracy. In Case 6 the *x*-ray showed a fracture which was the starting point of the infection. In Case 3 a definite sequestrum was found to be present. Good *x*-rays are difficult to obtain of the condyle and upper part of the ramus, but when obtained may be of the greatest aid.

A careful study of the plates may rule out sarcoma and syphilis in certain doubtful cases, but at times both cancer or sarcoma accompanied by bone destruction are difficult to differentiate from osteomyelitis by any known means except the microscope.

TREATMENT

In acute cases affecting the body of the mandible the general rule for treatment should be to remove the facial wall of the lower jaw through an external incision, exposing the inferior dental canal (Fig. 1). In this way all large marrow spaces are opened, the best possible drainage obtained, the firm inner wall is left which keeps the jaw in shape and an opportunity is given to retain the teeth. A good example of the result of this procedure is seen in Case 6, in which the disease was checked and all of the teeth retained. That this method is far superior to incisions in the mouth is obvious and needs no discussion. The gravity of the disease demands radical treatment and leaves us little choice as to whether scars should be left or not.

Subacute and chronic cases are a law unto themselves and no definite method of treatment can be laid down for their relief. In general we may say that the treatment of each case is a hunt for diseased teeth, pockets of pus and sequestra. Sequestra representing the entire thickness of the jaw should be left until a firm involucrum is formed in order to minimize deformity. These cases need careful watching, as acute exacerbations occur frequently and are troublesome and dangerous.

Trismus is frequently an annoying feature and rectal or nasal feeding may be necessary. Hot applications externally may give some relief from this condition, which is usually a combination of muscular spasm and inflammatory edema.

Lymphadenitis and angina Ludovici may occur at any time. The latter demands immediate surgical intervention.

DEFORMITY

After loss of large portions of the jaw, as in Case 3, a certain amount of deformity results with shortening of the body on the affected side. Certain plastic operations have been devised to relieve this condition and it seems probable that bone might be implanted successfully in order to overcome the difficulty. Up to date I have been unable to find a patient who was willing to undergo the ordeal after recovering from an acute process in the jaw.

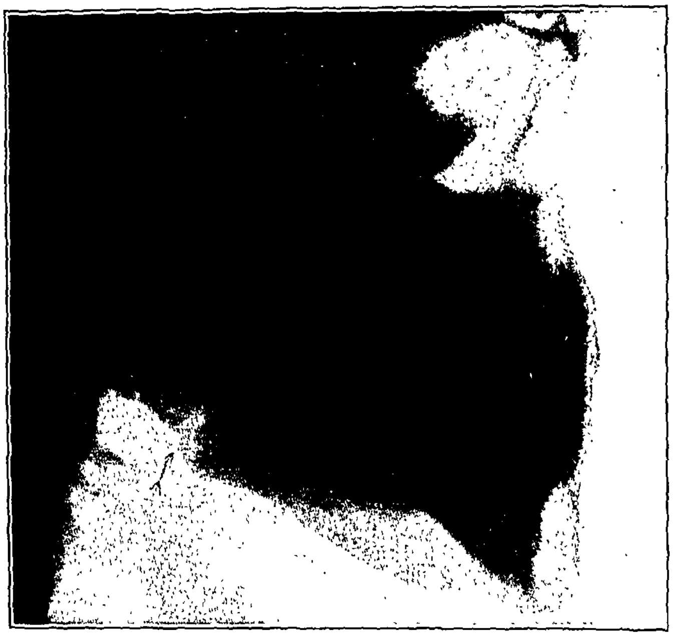

Fig. 6.—From *x*-ray of Patient 6; note fracture.

SUMMARY OF CASES

CASE 1.—A man, aged 41, entered hospital May 5, 1905; *no* history of injury. Illness had begun two weeks previously with pain and swelling in cheek; now showed indurated swelling of lower jaw to the left of the median line the size of half an orange. Operation was performed; chin incised and bone curetted. Patient returned to hospital Oct. 3, 1905; had several sinuses which had never healed. Examination showed two sinuses leading to bone near median line. Incision from one angle of the jaw to the other showed the whole jaw to be necrotic and large amount of bone was removed. Patient returned to hospital again a year later when more dead bone was removed from the left side of the jaw. Since then he has been well.

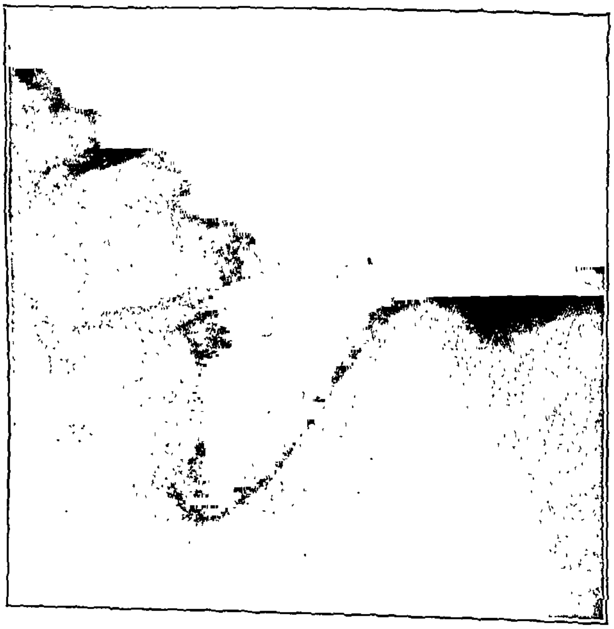

Fig. 7.—From *x*-ray of Patient 9; note absence of condyle and upper part of ramus.

CASE 2.—A man, aged 56, for ten weeks had pain in lower jaw following extraction of a molar tooth, with trismus, painful deglutition and constant pain which was worse at night; he had lost thirty pounds in ten weeks. At operation the sequestrum was *removed from left side of jaw which consisted* of alveolar process and part of body. Uneventful recovery.

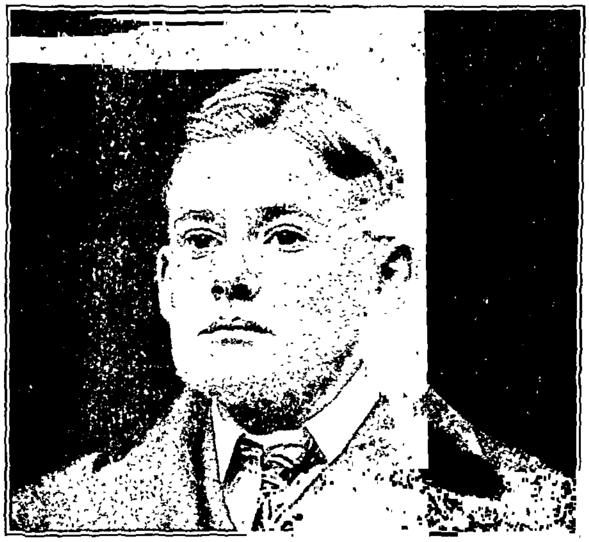

Fig. 8.—From photograph of Patient 10; note swelling on right of lower jaw.

CASE 3.—A girl, aged 9, five months previous to examination had had abscessed molar removed without relief from pain; later had all of teeth removed on same side without relief. The jaw became swollen and tender and was lanced several times. Examination showed whole face of affected side much swollen with external sinus at angle of the jaw (Fig. 2). *X*-ray showed large sequestrum (Fig. 3). Operation was performed and sequestrum consisting of large part of the body and *all the ramus on right side removed; fairly firm* involucrum present.

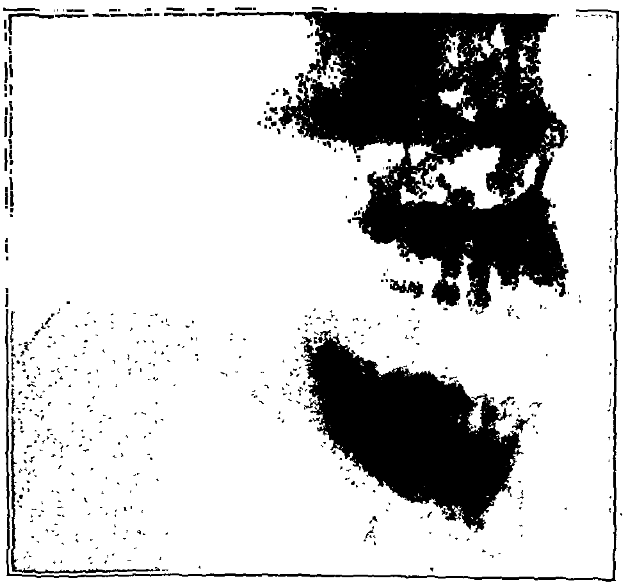

Fig. 9.—From *x*-ray of Patient 10; note thickening of periosteum.

opening. Similar instances are reported by Perthes. In Case 9 of this series there was a sinus in the external auditory canal which on superficial examination resembled otitis media.

These teeth sinuses are particularly frequent in the region of the chin, where a dead incisor or cuspid may be the offending agent. Extraction of these dead teeth may be insufficient for cure, since a pocket of pus and granulations may be present at the apex of the root. Case 10 in the following series is an example.

DIAGNOSIS

Occasional difficulties in diagnosis will be experienced, but they are fortunately rare. Cases of malignant disease with secondary infection are stumbling-blocks which occur now and then. Syphilis and actinomycosis may, of course, confuse. Suppurating dentigerous cysts have been seen often enough to make one consider the possibility. Phosphorus necrosis is extremely rare at the present time. In all of the above conditions, except syphilis, the treatment is surgical and at operation there is rarely any difficulty as to the best course to pursue.

The most valuable information may be obtained by the x-ray in cases in which the disease is localized, in which there is a definite sequestrum or in which fracture is a starting-point of the disease. In Cases 10 and 11 foci of suppuration were located with accuracy. In Case 6 the x-ray showed a fracture which was the starting point of the infection. In Case 3 a definite sequestrum was found to be present. Good x-rays are difficult to obtain of the condyle and upper part of the ramus, but when obtained may be of the greatest aid.

A careful study of the plates may rule out sarcoma and syphilis in certain doubtful cases, but at times both cancer or sarcoma accompanied by bone destruction are difficult to differentiate from osteomyelitis by any known means except the microscope.

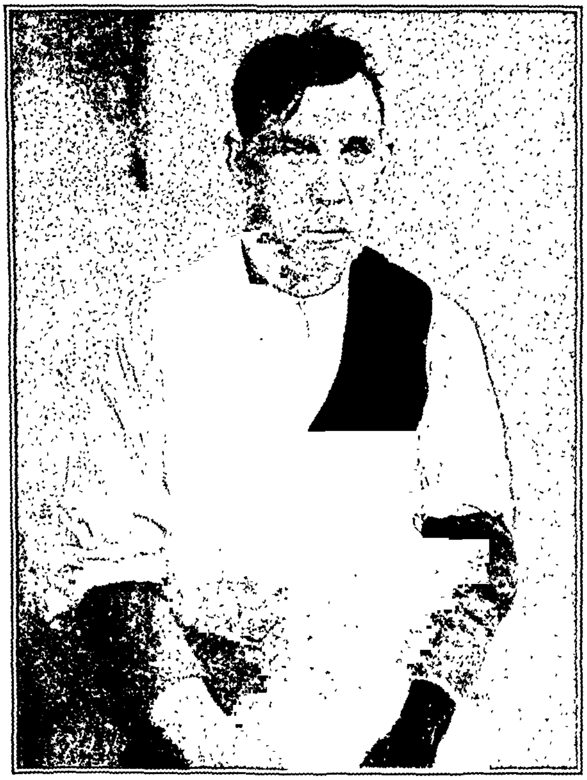

Fig. 4.—From photograph of Patient 6, front view.

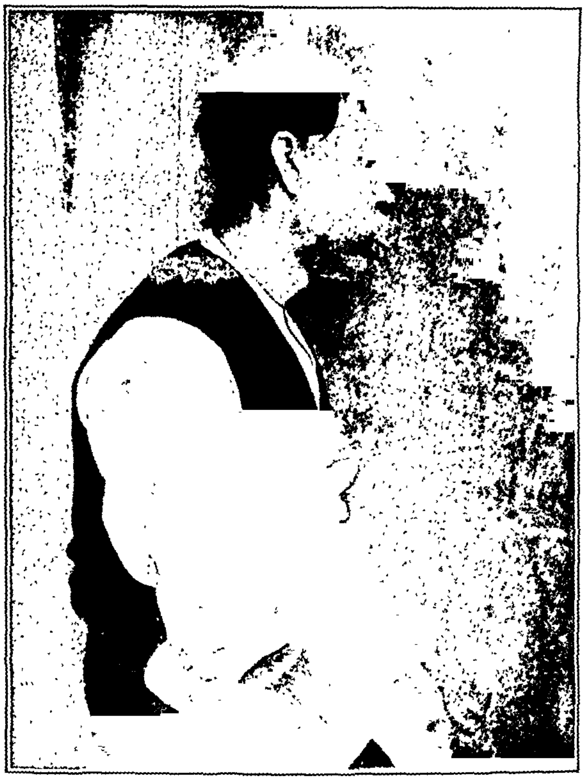

Fig. 5.—From photograph of Patient 6, side view.

TREATMENT

In acute cases affecting the body of the mandible the general rule for treatment should be to remove the facial wall of the lower jaw through an external incision, exposing the inferior dental canal (Fig. 1). In this way all large marrow spaces are opened, the best possible drainage obtained, the firm inner wall is left which keeps the jaw in shape and an opportunity is given to retain the teeth. A good example of the result of this procedure is seen in Case 6, in which the disease was checked and all of the teeth retained. That this method is far superior to incisions in the mouth is obvious and needs no discussion. The gravity of the disease demands radical treatment and leaves us little choice as to whether scars should be left or not.

Subacute and chronic cases are a law unto themselves and no definite method of treatment can be laid down for their relief. In general we may say that the treatment of each case is a hunt for diseased teeth, pockets of pus and sequestra. Sequestra representing the entire thickness of the jaw should be left until a firm involucrum is formed in order to minimize deformity. These cases need careful watching, as acute exacerbations occur frequently and are troublesome and dangerous.

Trismus is frequently an annoying feature and rectal or nasal feeding may be necessary. Hot applications externally may give some relief from this condition, which is usually a combination of muscular spasm and inflammatory edema.

Lymphadenitis and angina Ludovici may occur at any time. The latter demands immediate surgical intervention.

DEFORMITY

After loss of large portions of the jaw, as in Case 3, a certain amount of deformity results with shortening of the body on the affected side. Certain plastic operations have been devised to relieve this condition and it seems probable that bone might be implanted successfully in order to overcome the difficulty. Up to date I have been unable to find a patient who was willing to undergo the ordeal after recovering from an acute process in the jaw.

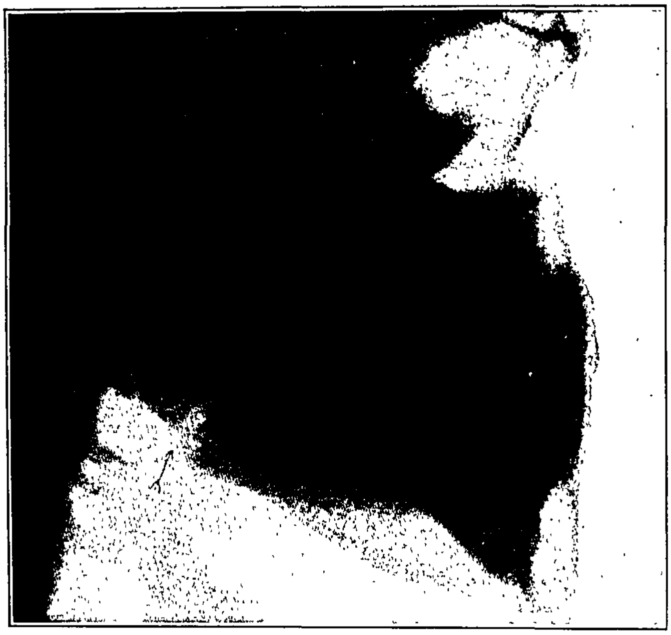

Fig. 6.—From *x*-ray of Patient 6; note fracture.

SUMMARY OF CASES

Case 1.—A man, aged 41, entered hospital May 5, 1905; no history of injury. Illness had begun two weeks previously with pain and swelling in cheek; now showed indurated swelling of lower jaw to the left of the median line the size of half an orange. Operation was performed; chin incised and bone curetted. Patient returned to hospital Oct. 3, 1905; had several sinuses which had never healed. Examination showed two sinuses leading to bone near median line. Incision from one angle of the jaw to the other showed the whole jaw to be necrotic and large amount of bone was removed. Patient returned to hospital again a year later when more dead bone was removed from the left side of the jaw. Since then he has been well.

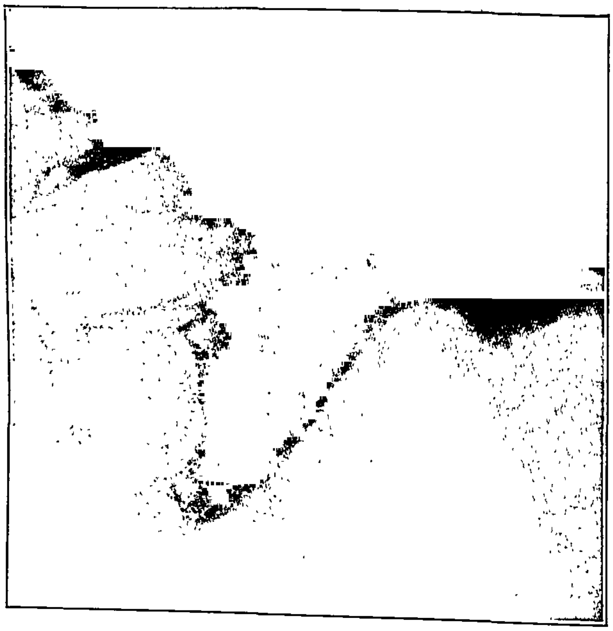

Fig. 7.—From *x*-ray of Patient 9; note absence of condyle and upper part of ramus.

Case 2.—A man, aged 56, for ten weeks had pain in lower jaw following extraction of a molar tooth, with trismus, painful deglutition and constant pain which was worse at night; he had lost thirty pounds in ten weeks. At operation the sequestrum was removed from left side of jaw which consisted of alveolar process and part of body. Uneventful recovery.

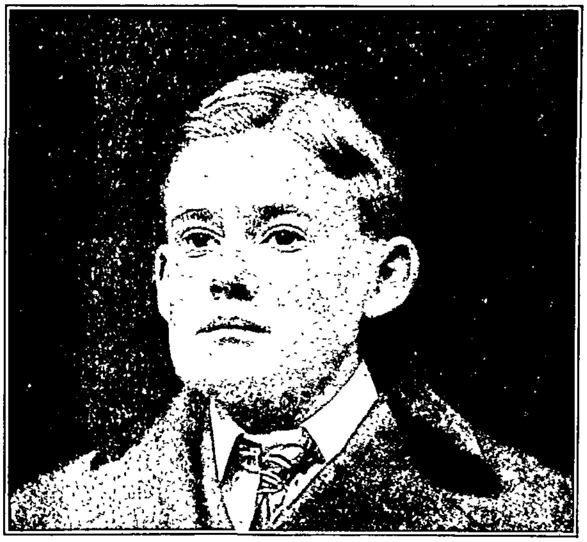

Fig. 8.—From photograph of Patient 10; note swelling on right of lower jaw.

Case 3.—A girl, aged 9, five months previous to examination had had abscessed molar removed without relief from pain; later had all of teeth removed on same side without relief. The jaw became swollen and tender and was lanced several times. Examination showed whole face of affected side much swollen with external sinus at angle of the jaw (Fig. 2). *X*-ray showed large sequestrum (Fig. 3). Operation was performed and sequestrum consisting of large part of the body and all the ramus on right side removed; fairly firm involucrum present.

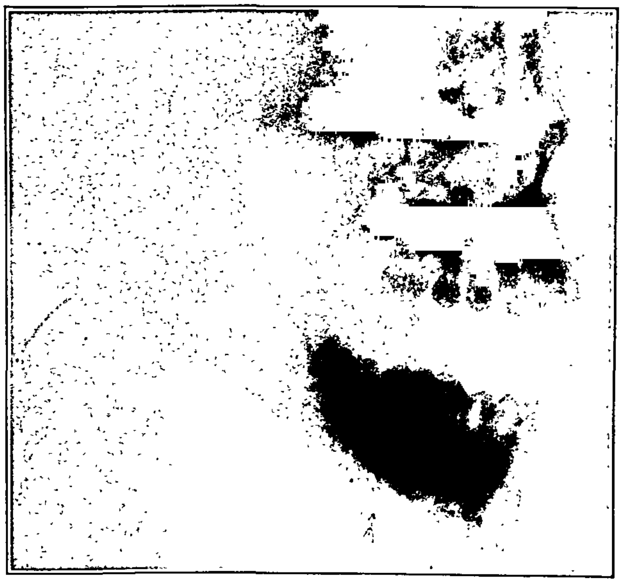

Fig. 9.—From *x*-ray of Patient 10; note thickening of periosteum.

Case 4.—A girl, aged 3, had lost all teeth of lower jaw with alveolar process during an attack of noma. Lower lip was adherent to jaw with mouth about three-quarters of an inch in diameter.

Case 5.—A boy, aged 7, whose lower jaw had been fractured during extraction of a tooth fourteen months previous to the time he came under observation, after this had an abscess under the jaw which was opened several times. At operation sequestrum was removed from left half of body of lower jaw. Recovery was uneventful.

Case 6.—A man, aged 50, received blow on chin Feb. 24, 1809; twenty-four hours later he had acute pain with trismus, difficulty in swallowing and in speech. Examination showed diffuse swelling (Figs. 4 and 5); abscess was opened three days afterward. *X*-ray showed a fracture of the lower jaw through the last molar (Fig. 6). Six weeks later, owing to persistent pain and swelling, the facial wall of lower jaw was removed with good recovery.

Case 7.—A boy, aged 19, six years before operation was kicked in the chin, following which an abscess developed and was opened; sinus was persistent. At operation sequestrum was removed from under incisor teeth; recovery was uneventful.

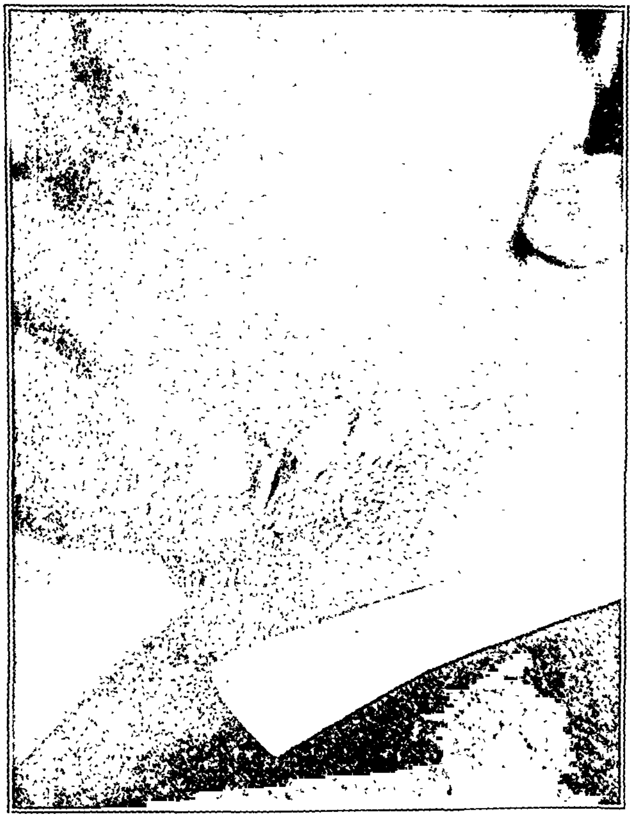

Fig. 10.—From photograph of Patient 11; sinus at angle of jaw.

Case 8.—A girl, aged 11, two and a half years before operation was struck in the chin by a blow of the fist. Following this an abscess developed, which was opened, leaving a persistent sinus. At operation the sinus led into a cavity under the first molar, into which the root projected. Tooth was extracted and cavity curetted; recovery was uneventful.

Case 9.—A man, aged 42, was struck in the chin by a limb of a tree three months before examination; he was rendered unconscious and awoke in hospital. At that time diffuse swelling of left side of face with facial paralysis and bleeding from the left ear were present; the patient was in hospital six weeks. He now sought aid on account of discharging ear with pain in region of ramus of jaw on the same side. Examination showed sinus leading forward from cartilaginous canal to region of glenoid fossa. At operation necrotic condyle was found broken off and lying in zygomatic fossa (Fig. 7). Recovery uneventful.

Case 10.—A boy, aged 13, had had abscessed bicuspid removed six weeks previously. The mucous membrane healed, but persistent swelling of the whole lower jaw and cheek remained (Fig. 8). This swelling varied and at times partly closed the right eye. *X*-ray showed thickening of the periosteum with increased density of the bone (Fig. 9). At operation a cavity, the size of a cherry, containing pus and granulations was found below the bicuspid. In this case there was no sinus. Uneventful recovery.

Case 11.—A boy, aged 20, for ten months had had a discharging sinus which appeared spontaneously after an acute swelling in the region of the angle of the jaw (Fig. 10). *X*-ray showed area of dense bone in the ramus suggesting a sequestrum (Fig. 11). At operation a small bone abscess was found in lower part of ramus.

Case 12.—A woman, aged 29, a few weeks before operation had the lower right bicuspid extracted on account of pain; six weeks before examination had three lower molar teeth extracted for same reason with no relief. Two weeks before examination incisor teeth were removed without relief. Right side of jaw began to swell five months previously; at times the patient had trismus and difficulty in swallowing. Examination showed lower jaw on right swollen and tender; remaining incisor teeth loose. At operation lower incisors were removed and sequestrum consisting of part of body removed through the mouth. One month later another piece of necrotic bone was removed from jaw near the median line.

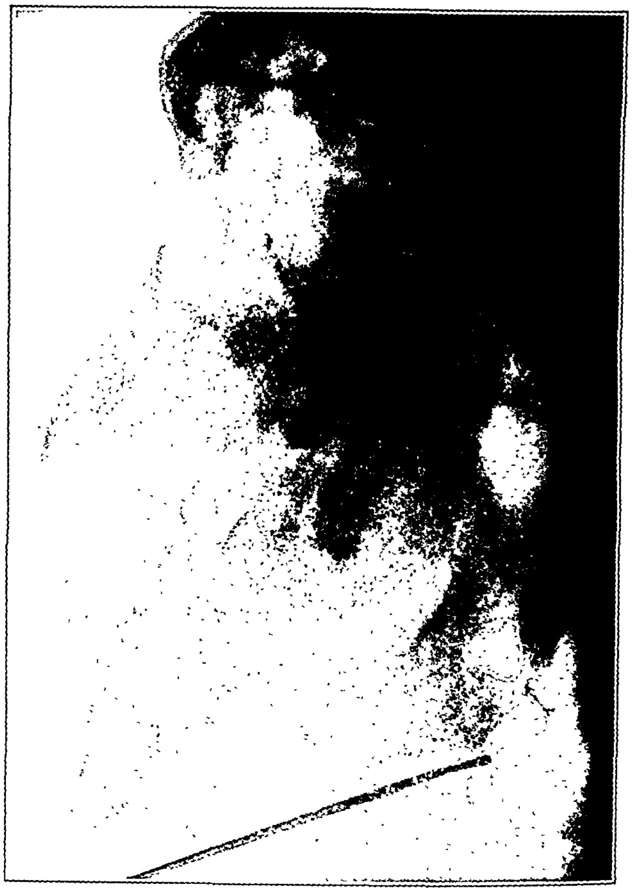

Fig. 11.—From *x*-ray of Patient 11; note focus in ramus.

In closing I desire to thank Drs. Munro and Bottomly for the use of the clinic at the Carney Hospital and opportunity furnished for the study of their cases.

ABSTRACT OF DISCUSSION

Dr. Eugene S. Talbot, Chicago: Few physicians and surgeons are able to differentiate conditions due to diseased pulps, death of pulp with alveolar abscess and osteomyelitis due to other causes. There is not a stomatologist who, in his medical life, has not met many surgeons who know nothing of the subject. I could cite 15 or 20 cases in which surgeons have operated on jaws for simple alveolar abscess. The essayist, from his experience, can discriminate between these conditions, which is important in treatment. Patients with osteomyelitis due to dead pulps can be sent to the stomatologist and successfully treated, thus avoiding unnecessary mutilation.

DR. GEORGE V. I. BROWN, Milwaukee: Every point of this paper has been proved by slides. The changes occurring in the bone structure in degeneration and regeneration, and the cases illustrated are exceedingly interesting. I was called the other day to see a little boy in Nashvillle with congenital ankylosis, his jaw was very much drawn to one side, even more than the one shown by the essayist. In another case, a little girl of six with an ankylosed mandible, I operated and gave relief and she can now open her mouth; but I do not really know what caused the ankylosis in either of these cases. I would be glad to have the doctor tell us more of his conclusions, because his radiograph pictures are much clearer than any I have been able to secure.

DR. STEWART L. MCCURDY, Pittsburg, Pa.: In no case, especially in the suppurative stage, will it be possible to tell whether the disease was primarily periostitis or osteomyelitis. In ankylosis we will find a history of suppurative middle-ear disease. The disease extends into the temporo-mandibular joint and results in its destruction and subsequent ankylosis. That is the condition I found in a great many of these cases. The treatment is the removal of the head of the bone.

In the treatment of these cases I have removed half of the bone in one case and nearly two-thirds in another case. In another, the bone was denuded from the angle throughout its extent of the ramus, and I could pass a probe along the entire surfaces of the rami on both sides. Fifty per cent. of these cases are specific, and repair will only take place under potassium iodid treatment. This was followed by readhesion of the periosteum to the bone and recovery under specific medication.

DR. H. H. GERMAIN, Boston: This man who had a fracture of the condyle had a double fracture of the lower jaw. The second one just below the region of the condyle was not discovered. The first fracture was treated, and he developed an apparent suppurative condition of the middle-ear. He had never had any middle-ear disease. This led me to believe that it was a condition following the fracture. I passed a probe down to the sinus anteriorly and felt sure that if I followed the sinus I would go down to the condyle. The condyle was found broken off and necrotic and was removed. He got a very good jaw, considering the fact that he had been suffering for four months. I do not think it is a fair statement that 50 per cent. of cases of osteomyletis are due to syphilis. Very much less than this, if any, is more nearly true.

THE WASSERMANN REACTION IN ITS RELATION TO DISEASES OF THE CENTRAL NERVOUS SYSTEM *

B. SACHS, M.D.

NEW YORK

Neurologists will appreciate the importance of a method which will enable them to state positively whether or not a suspicion of syphilis is justified, or whether every thought of syphilitic disease may be eliminated from the consideration of a given case. Just such service as this the complement-fixation test of Wassermann has promised to render. It seemed well worth while to become thoroughly conversant with the method, the details of which will be described by others, and during a period of very nearly one year to submit to this test as many patients as possible suffering from nervous disease, so as to determine whether or not it would be of service in the diagnosis and treatment of nervous and mental disorders. Shortly after the publication of the investigations of Wassermann, Plaut, Bruck, Neisser, Georg Meier, Porges, Taylor, Citron and others, the inference was drawn that the Wassermann reaction would be of great service in the diagnosis of locomotor ataxia and general paresis—the two diseases which have long since been held to be due to preceding syphilitic infection. Dr. Nonne,[1] of Hamburg, whom we are fortunate enough to have with us to-day, was among the first to make the attempt to determine the general value of the Wassermann reaction in neurologic practice. In this country Drs. Noguchi, Castelli, Gay, Butler, Swift, and Fox have taken up the Wassermann test. I have felt from the very beginning that, while it might be desirable to have further corroborative evidence in tabes dorsalis and dementia paralytica, such corroborative evidence is not often needed and that it would be much more important, as my own hospital experience has taught me, to possess a test which would help to establish the differential diagnosis between a number of other conditions. It seemed much more important, for instance, to be able to differentiate between disseminated sclerosis and cerebrospinal syphilis, between a central gliosis or a specific central myelitis; to decide whether the symptoms of intracranial pressure were due to malignant neoplasm or to a gummatous meningitis; and it was for the purpose of determining the value of the Wassermann test in this larger group of cases that liberal use has been made of the reaction in cases coming under my notice in my hospital[2] as well as in private practice.

First, a few words as to the reaction. It has shared the fate of all new diagnostic methods in receiving either excessive praise or excessive condemnation. It is only by prolonged experience that we can arrive at the exact truth. The test is cumbersome, is not altogether easy to acquire (laboratory practice of a few months is demanded), and the performance of it calls for an unusual amount of patience and of time on the part of the investigator. It will, of course, be far easier to carry out the test in an established laboratory, but it is not altogether beyond the capacity of a private laboratory such as I have been able to arrange, in association with Dr. Castelli, to whose assistance and cooperation I am deeply indebted. The chief defect of the test is that it is altogether a relative one and that the question of the inhibition of hemolysis can be determined only by a comparison with control tubes in which the syphilitic extract or the specific serum is wanting. There are so many possibilities of error in the performance of the test that credit can be given to the results only if those working by it are known to be thoroughly conscientious and capable. It is entirely natural that attempts have already been made to modify the Wassermann technic so as to place the reaction within easy reach of every practitioner. Among those who have made the laudable attempt to simplify the original reaction has been Noguchi, and you will no doubt hear from him to-day to what extent we may substitute his modification for the original Wassermann method. It is very gratifying, however, to be able to state that in a series of forty-five cases examined by Dr. Castelli and myself, according to the original Wassermann method, and by Dr. Noguchi ac-

The first fracture was treated, and he developed an apparent suppurative condition of the middle-ear. He had never had any middle-ear disease. This led me to believe that it was a condition following the fracture. I passed a probe down to the sinus anteriorly and felt sure that if I followed the sinus I would go down to the condyle. The condyle was found broken off and necrotic and was removed. He got a very good jaw, considering the fact that he had been suffering for four months. I do not think it is a fair statement that 50 per cent. of cases of osteomyletis are due to syphilis. Very much less than this, if any, is more nearly true.

THE WASSERMANN REACTION IN ITS RELATION TO DISEASES OF THE CENTRAL NERVOUS SYSTEM [*]

B. SACHS, M.D.
NEW YORK

Neurologists will appreciate the importance of a method which will enable them to state positively whether or not a suspicion of syphilis is justified, or whether every thought of syphilitic disease may be eliminated from the consideration of a given case. Just such service as this the complement-fixation test of Wassermann has promised to render. It seemed well worth while to become thoroughly conversant with the method, the details of which will be described by others, and during a period of very nearly one year to submit to this test as many patients as possible suffering from nervous disease, so as to determine whether or not it would be of service in the diagnosis and treatment of nervous and mental disorders. Shortly after the publication of the investigations of Wassermann, Plaut, Bruck, Neisser, Georg Meier, Porges, Taylor, Citron and others, the inference was drawn that the Wassermann reaction would be of great service in the diagnosis of locomotor ataxia and general paresis—the two diseases which have long since been held to be due to preceding syphilitic infection. Dr. Nonne,[1] of Hamburg, whom we are fortunate enough to have with us to-day, was among the first to make the attempt to determine the general value of the Wassermann reaction in neurologic practice. In this country Drs. Noguchi, Castelli, Gay, Butler, Swift, and Fox have taken up the Wassermann test. I have felt from the very beginning that, while it might be desirable to have further corroborative evidence in tabes dorsalis and dementia paralytica, such corroborative evidence is not often needed and that it would be much more important, as my own hospital experience has taught me, to possess a test which would help to establish the differential diagnosis between a number of other conditions. It seemed much more important, for instance, to be able to differentiate between disseminated sclerosis and cerebrospinal syphilis, between a central gliosis or a specific central myelitis; to decide whether the symptoms of intracranial pressure were due to malignant neoplasm or to a gummatous meningitis; and it was for the purpose of determining the value of the Wassermann test in this larger group of cases that liberal use has been made of the reaction in cases coming under my notice in my hospital[2] as well as in private practice.

First, a few words as to the reaction. It has shared the fate of all new diagnostic methods in receiving either excessive praise or excessive condemnation. It is only by prolonged experience that we can arrive at the exact truth. The test is cumbersome, is not altogether easy to acquire (laboratory practice of a few months is demanded), and the performance of it calls for an unusual amount of patience and of time on the part of the investigator. It will, of course, be far easier to carry out the test in an established laboratory, but it is not altogether beyond the capacity of a private laboratory such as I have been able to arrange, in association with Dr. Castelli, to whose assistance and cooperation I am deeply indebted. The chief defect of the test is that it is altogether a relative one and that the question of the inhibition of hemolysis can be determined only by a comparison with control tubes in which the syphilitic extract or the specific serum is wanting. There are so many possibilities of error in the performance of the test that credit can be given to the results only if those working by it are known to be thoroughly conscientious and capable. It is entirely natural that attempts have already been made to modify the Wassermann technic so as to place the reaction within easy reach of every practitioner. Among those who have made the laudable attempt to simplify the original reaction has been Noguchi, and you will no doubt hear from him to-day to what extent we may substitute his modification for the original Wassermann method. It is very gratifying, however, to be able to state that in a series of forty-five cases examined by Dr. Castelli and myself, according to the original Wassermann method, and by Dr. Noguchi ac-

cording to his recent modification, the reactions have tallied in all but four cases. Such discrepancies as have occurred will no doubt be accounted for by greater perfection in the technic of both methods. Noguchi's method appears to be unusually sensitive, and we trust that he will be able to satisfy all of us that a positive Noguchi reaction means active lues, as I am fully persuaded a positive Wassermann reaction does.

---

[*] Read in the Section on Nervous and Mental Diseases of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

2. I am indebted to Dr. Gregory of Bellevue Hospital, and to the members of the house-staff at Mt. Sinai Hospital, Drs. Sophian, Bass and Muncker, for much amiable assistance.

I must leave the determination of methods and the description of their imperfections, if there be such, to others. I am concerned in this paper with the relation of the Wassermann reaction to diseases of the central nervous system, and, in order to avoid criticism as to the method employed, Dr. Castelli and myself have adhered closely to the technic of the Wassermann school, as we acquired it in Berlin, and have not deviated from the original method in any particular, except that we have substituted the alcoholic extract of the syphilitic fetal liver for the aqueous extract. This is supposed by some to make the reaction less sensitive. Wassermann himself was opposed to the introduction of the alcoholic extract for a time, but this point, I believe, has now been yielded by him and his followers. At all events, using the alcoholic extract has given us most satisfactory results, as was proved by a large series of tests in which all precautions regarding the necessary controls were employed. It is well known, no doubt, by the majority of those present, that the theory on which the reaction was founded has received rather a serious blow, inasmuch as the inhibition of hemolysis was obtained not only when syphilitic liver extract was used, but also when the extract of normal liver was employed and when other lipoid substances were used.[3] Whatever the explanation of this may prove to be, the fact remains that in an unusually high percentage of cases of syphilitic and [illegible] e blood serum, if examined [illegible]'s directions, gives a very definite inhibition of hemolysis, whereas complete hemolysis ensues in the serum taken from patients who are not afflicted with any syphilitic taint.

The conditions of practice and even of my hospital service have made it necessary to restrict my examinations largely to the examination of the blood serum. No doubt Nonne is correct in insisting that the full truth can be obtained only after a consideration of the cellular elements in the spinal fluid, the globulin content, and the specific reaction of blood and serum and of the spinal fluid. In a small number of the cases (15) the spinal fluid has been examined, and in one case of a child, when it was impossible to obtain sufficient blood for the Wassermann test, a blister was drawn—following the suggestion of Dr. Kaplan to one of my assistants —and serum obtained in this fashion. I wish in this communication to give some of the more important results obtained in a series of about 250 cases. In many of these several tests were made.

All investigators are agreed as to the value of a positive Wassermann reaction. If it signifies anything at all, it indicates a more or less active luetic process somewhere in the system. A negative reaction by common consent does not preclude the presence of syphilis and yet a negative reaction, it seems to me, often gives valuable information. In the vast majority of cases in which the negative reaction is obtained, the thought of syphilis may be dismissed. In a large number of others, however, in which a positive reaction has been found present at the beginning of the disease, and in which a negative reaction has been obtained in the course of or after prolonged treatment, it is only fair to assume that the syphilitic virus has been neutralized as a result of the therapeutic measures employed.[4] In this connection it is important to note that a positive Wassermann reaction may often be wanting in spite of the true syphilitic nature of the disease, if intense or prolonged antisyphilitic medication had been employed before the first test was made. As a matter of routine in my hospital practice the rule had been established that neither mercury nor iodids were to be administered to any patient until the Wassermann test had been done. Assuming, then, that a Wassermann reaction may furnish corroborative evidence as to the presence or absence of an active syphilitic virus, let me give in some detail the results obtained in various groups of cases.

I. IN TABES AND GENERAL PARESIS

As I have intimated before, the reaction is hardly needed as corroborative evidence in these two conditions, because in fully 95 per cent. of the cases the diagnosis can be safely made. The chief difficulties have been experienced in the differential diagnosis, in former years, between tabes dorsalis and syphilitic spinal disease simulating tabes, or between general paresis and specific pseudoparesis. But the Wassermann reaction will be expected to be positive in all of these conditions and can, therefore, throw little light on the exact nature of the morbid process. It may be of some value in those cases in which the differential diagnosis has to be made between general paresis and neurasthenia. The preponderance of opinion would seem to favor the idea that if a Wassermann reaction is positive, the disease is necessarily paresis and not neurasthenia. But if we suppose that the neurasthenic individual has had a preceding syphilitic infection, as well he might have, it would not be fair to infer general paresis merely because the patient gives a positive reaction. And this leads me to the first opinion which I wish to express, as a result of my experience, and that is that a positive Wassermann reaction implies an active luetic process somewhere in the system. Any inference beyond this point seems here hardly to be justifiable. I can in this way account for the discrepancy between the figures published abroad regarding tabes and general paresis and those which have been obtained by Dr. Castelli and myself. We have not found a positive reaction to be universally present in general paresis and almost universally present in tabes, as has been published by so many writers abroad. The presence or absence of the reaction, even in tabes and general paresis, depends more or less on the active luetic virus and less on the terminal cortical or spinal cord changes which are responsible for the symptoms of general paresis or of tabes dorsalis. Our own results in tabes and general paresis have been as shown in the accompanying table.

In this series of 28 cases of tabes, 18, or 64.3 per cent., were positive and 10, or 35.7 per cent., were negative. For the purpose of this table I have considered all weak positive cases of the same value as the more positive ones. This percentage is a little lower than that of some of the former investigators, though it is even a little higher than the statistics of Hoehne,

who found a positive reaction in 60 per cent. of 45 cases of tabes, but he has in his list 12 cases of doubtful tabes in which there was a positive reaction in 41.7 per cent. In our list we have had no doubtful cases of tabes, and I take it that in every neurologic clinic there will surely not be 25 per cent. of doubtful cases of tabes dorsalis as there are in this list, which has been issued from a dermatologic and not a neurologic clinic. Wassermann and Plaut found a positive reaction in 70 per cent. of their tabic patients; others claim as high as 90 per cent., and Nonne apparently obtained a positive reaction in 90 per cent. of the blood examinations and 50 per cent. in the examinations of the spinal fluid. Our own figures are, therefore, in general agreement with those who place the percentage somewhere between 65 and 70 per cent. The character of the patients has much to do with the percentages of the reaction. Of the 28 cases of tabes referred to in this paper, 19 were observed in my private practice, and of these at least half were patients who had been under constant observation over a period varying between three and ten years and all of them had received much treatment. Even before the importance of the Wassermann reaction had been disclosed I had been in the habit of subjecting my tabic patients to a course of sublimate injections at least twice a year. This will account for the fact that of the nine negative cases of tabes in my series seven were cases of patients who had been subjected to this line of treatment. It can, therefore, be seen readily enough that if I were to tabulate only hospital cases and those seen for the first time during the past year the percentage of positive reactions would be very much higher. It is also worthy of note that all the female tabic patients, as well as all the female general paretics, gave a positive reaction. A reaction which was positive in a number of tabic patients before treatment was begun gave a negative reaction after a course of several weeks' treatment had been persisted in.

---

[3] Professor Kopp (München med. Wchnschr., May 11, 1909) has endeavored (I think, in vain) to minimize the universal enthusiasm regarding the clinical value of this method. Since writing the above, Neisser has spoken frankly of its tremendous importance.

[4] Since writing the above, corroboration of this view has come to me in the article of Hoehne (Berl. klin. Wchnschr., May 10, 1909) entitled: Die Wassermann'sche Reaktion und ihre Beeinflussung durch die Therapie.

* Juvenile general paralysis

In spite of these high percentages we can not expect much help from the reaction in those cases of spinal or cerebrospinal lues in which the tabic type predominates, for in both these groups of cases a positive reaction might be obtained and yet no light whatever will be thrown on the spinal character of the morbid changes underlying the symptoms. In every case in which a positive reaction was obtained, specific treatment was pushed with much more energy than would otherwise have been the case.

Among these cases of tabes I wish to single out two for special mention. They have both been under observation for many years, the one during a period of four, the other during a period of ten years at least, and both of these were puzzling for a long period because they presented no other symptom than a dissociation of sensation within the distribution of the fifth nerve, the affection in one case becoming bilateral, in the other remaining unilateral. Both these patients—the one a man of 35, the other of 38 years, the one a merchant and the other a machinist—presented positive reactions. The one patient was observed for years before any other symptoms of tabes were in evidence, but to the dissociated sensation of the trigeminal distribution has now been added a loss of knee-jerks and an ataxic gait, whereas the other still presents no other symptom except a difference in the knee-jerks and some vague and occasional lightning pains. After finding a positive reaction in these two cases, strenuous mercurial treatment was given, always by hypodermatic injections, and strangely enough in both these cases the trigeminal symptoms have been distinctly diminished since the hypodermatic injections were begun, and in both the tabic process seems for the present to have come to a standstill.

Of the 31 cases of general paresis, 32.3 per cent. gave a negative reaction and in 67.7 per cent. the reaction was positive. It will be seen that these percentages are almost identical with those obtained in tabes, whereas other observers have recorded higher percentages. The same explanation that I have given in the cases of tabes will hold to a certain degree for general paresis. All of the cases of general paresis were progressive in their symptoms in spite of the mercurial treatment to which the patients had been subjected. Among the list of cases are several that have lasted a period of two years or more, and all of these cases of old standing gave a negative reaction. Another possible explanation for the low percentages of positive reactions in my cases may be the fact that a number of these cases were in the psychopathic ward of Bellevue Hospital, where patients are retained only over a period of four or five days and where the diagnosis often has to be made hastily, so that there is a bare possibility that some of those which have been classed as cases of general paresis might possibly have belonged to the category of doubtful cases. I have placed in a separate series 7 cases which were unquestionably doubtful ones and of these 7, 5 gave a negative reaction and 2 a positive reaction, one of these 2 positive reactions being weak positive. The contrast between these doubtful cases and undoubtedly genuine cases is striking enough to make us appreciate the value of a positive reaction when it is found, but in the case of general paresis again the finding of a positive reaction does not help us materially in making a differential diagnosis between typical general paresis and syphilitic pseudoparesis. A most interesting example of this character was that of a patient (No. 24) who had had tabes for many years and in addition to these symptoms of tabes had passed through attacks which would ordinarily be classified as manic or manic-depressive attacks, with occasional speech disturbances that were a little like those of general paresis and with occasional delusions of an expansive character. The diagnosis of general paresis was made offhand by a num-

cording to his recent modification, the reactions have tallied in all but four cases. Such discrepancies as have occurred will no doubt be accounted for by greater perfection in the technic of both methods. Noguchi's method appears to be unusually sensitive, and we trust that he will be able to satisfy all of us that a positive Noguchi reaction means active lues, as I am fully persuaded a positive Wassermann reaction does.

I must leave the determination of methods and the description of their imperfections, if there be such, to others. I am concerned in this paper with the relation of the Wassermann reaction to diseases of the central nervous system, and, in order to avoid criticism as to the method employed, Dr. Castelli and myself have adhered closely to the technic of the Wassermann school, as we acquired it in Berlin, and have not deviated from the original method in any particular, except that we have substituted the alcoholic extract of the syphilitic fetal liver for the aqueous extract. This is supposed by some to make the reaction less sensitive. Wassermann himself was opposed to the introduction of the alcoholic extract for a time, but this point, I believe, has now been yielded by him and his followers. At all events, using the alcoholic extract has given us most satisfactory results, as was proved by a large series of tests in which all precautions regarding the necessary controls were employed. It is well known, no doubt, by the majority of those present, that the theory on which the reaction was founded has received rather a serious blow, inasmuch as the inhibition of hemolysis was obtained not only when syphilitic liver extract was used, but also when the extract of normal liver was employed and when other lipoid substances were used.[3] Whatever the explanation of this may prove to be, the fact remains that in an unusually high percentage of cases of syphilitic and parasyphilitic diseases the blood serum, if examined according to Wassermann's directions, gives a very definite inhibition of hemolysis, whereas complete hemolysis ensues in the serum taken from patients who are not afflicted with any syphilitic taint.

The conditions of practice and even of my hospital service have made it necessary to restrict my examinations largely to the examination of the blood serum. No doubt Nonne is correct in insisting that the full truth can be obtained only after a consideration of the cellular elements in the spinal fluid, the globulin content, and the specific reaction of blood and serum and of the spinal fluid. In a small number of the cases (15) the spinal fluid has been examined, and in one case of a child, when it was impossible to obtain sufficient blood for the Wassermann test, a blister was drawn—following the suggestion of Dr. Kaplan to one of my assistants—and serum obtained in this fashion. I wish in this communication to give some of the more important results obtained in a series of about 250 cases. In many of these several tests were made.

All investigators are agreed as to the value of a positive Wassermann reaction. If it signifies anything at all, it indicates a more or less active luetic process somewhere in the system. A negative reaction by common consent does not preclude the presence of syphilis and yet a negative reaction, it seems to me, often gives valuable information. In the vast majority of cases in which the negative reaction is obtained, the thought of syphilis may be dismissed. In a large number of others, however, in which a positive reaction has been found present at the beginning of the disease, and in which a negative reaction has been obtained in the course of or after prolonged treatment, it is only fair to assume that the syphilitic virus has been neutralized as a result of the therapeutic measures employed.[4] In this connection it is important to note that a positive Wassermann reaction may often be wanting in spite of the true syphilitic nature of the disease, if intense or prolonged antisyphilitic medication had been employed before the first test was made. As a matter of routine in my hospital practice the rule had been established that neither mercury nor iodids were to be administered to any patient until the Wassermann test had been done. Assuming, then, that a Wassermann reaction may furnish corroborative evidence as to the presence or absence of an active syphilitic virus, let me give in some detail the results obtained in various groups of cases.

I. IN TABES AND GENERAL PARESIS

As I have intimated before, the reaction is hardly needed as corroborative evidence in these two conditions, because in fully 95 per cent. of the cases the diagnosis can be safely made. The chief difficulties have been experienced in the differential diagnosis, in former years, between tabes dorsalis and syphilitic spinal disease simulating tabes, or between general paresis and specific pseudoparesis. But the Wassermann reaction will be expected to be positive in all of these conditions and can, therefore, throw little light on the exact nature of the morbid process. It may be of some value in those cases in which the differential diagnosis has to be made between general paresis and neurasthenia. The preponderance of opinion would seem to favor the idea that if a Wassermann reaction is positive, the disease is necessarily paresis and not neurasthenia. But if we suppose that the neurasthenic individual has had a preceding syphilitic infection, as well he might have, it would not be fair to infer general paresis merely because the patient gives a positive reaction. And this leads me to the first opinion which I wish to express, as a result of my experience, and that is that a positive Wassermann reaction implies an active luetic process somewhere in the system. Any inference beyond this point seems here hardly to be justifiable. I can in this way account for the discrepancy between the figures published abroad regarding tabes and general paresis and those which have been obtained by Dr. Castelli and myself. We have not found a positive reaction to be universally present in general paresis and almost universally present in tabes, as has been published by so many writers abroad. The presence or absence of the reaction, even in tabes and general paresis, depends more or less on the active luetic virus and less on the terminal cortical or spinal cord changes which are responsible for the symptoms of general paresis or of tabes dorsalis. Our own results in tabes and general paresis have been as shown in the accompanying table.

In this series of 28 cases of tabes, 18, or 64.3 per cent., were positive and 10, or 35.7 per cent., were negative. For the purpose of this table I have considered all weak positive cases of the same value as the more positive ones. This percentage is a little lower than that of some of the former investigators, though it is even a little higher than the statistics of Hoehne,

who found a positive reaction in 60 per cent. of 45 cases of tabes, but he has in his list 12 cases of doubtful tabes in which there was a positive reaction in 41.7 per cent. In our list we have had no doubtful cases of tabes, and I take it that in every neurologic clinic there will surely not be 25 per cent. of doubtful cases of tabes dorsalis as there are in this list, which has been issued from a dermatologic and not a neurologic clinic. Wassermann and Plaut found a positive reaction in 70 per cent. of their tabic patients; others claim as high as 90 per cent., and Nonne apparently obtained a positive reaction in 90 per cent. of the blood examinations and 50 per cent. in the examinations of the spinal fluid. Our own figures are, therefore, in general agreement with those who place the percentage somewhere between 65 and 70 per cent. The character of the patients has much to do with the percentages of the reaction. Of the 28 cases of tabes referred to in this paper, 19 were observed in my private practice, and of these at least half were patients who had been under constant observation over a period varying between three and ten years and all of them had received much treatment. Even before the importance of the Wassermann reaction had been disclosed I had been in the habit of subjecting my tabic patients to a course of sublimate injections at least twice a year. This will account for the fact that of the nine negative cases of tabes in my series seven were cases of patients who had been subjected to this line of treatment. It can, therefore, be seen readily enough that if I were to tabulate only hospital cases and those seen for the first time during the past year the percentage of positive reactions would be very much higher. It is also worthy of note that all the female tabic patients, as well as all the female general paretics, gave a positive reaction. A reaction which was positive in a number of tabic patients before treatment was begun gave a negative reaction after a course of several weeks' treatment had been persisted in.

In the vast majority of cases in which the negative reaction is obtained, the thought of syphilis may be dismissed. In a large number of others, however, in which a positive reaction has been found present at the beginning of the disease, and in which a negative reaction has been obtained in the course of or after prolonged treatment, it is only fair to assume that the syphilitic virus has been neutralized as a result of the therapeutic measures employed.[4] In this connection it is important to note that a positive Wassermann reaction may often be wanting in spite of the true syphilitic nature of the disease, if intense or prolonged antisyphilitic medication had been employed before the first test was made. As a matter of routine in my hospital practice the rule had been established that neither mercury nor iodids were to be administered to any patient until the Wassermann test had been done. Assuming, then, that a Wassermann reaction may furnish corroborative evidence as to the presence or absence of an active syphilitic virus, let me give in some detail the results obtained in various groups of cases.

I. IN TABES AND GENERAL PARESIS

As I have intimated before, the reaction is hardly needed as corroborative evidence in these two conditions, because in fully 95 per cent. of the cases the diagnosis can be safely made. The chief difficulties have been experienced in the differential diagnosis, in former years, between tabes dorsalis and syphilitic spinal disease simulating tabes, or between general paresis and specific pseudoparesis. But the Wassermann reaction will be expected to be positive in all of these conditions and can, therefore, throw little light on the exact nature of the morbid process. It may be of some value in those cases in which the differential diagnosis has to be made between general paresis and neurasthenia. The preponderance of opinion would seem to favor the idea that if a Wassermann reaction is positive, the disease is necessarily paresis and not neurasthenia. But if we suppose that the neurasthenic individual has had a preceding syphilitic infection, as well he might have, it would not be fair to infer general paresis merely because the patient gives a positive reaction. And this leads me to the first opinion which I wish to express, as a result of my experience, and that is that a positive Wassermann reaction implies an active luetic process somewhere in the system. Any inference beyond this point seems here hardly to be justifiable. I can in this way account for the discrepancy between the figures published abroad regarding tabes and general paresis and those which have been obtained by Dr. Castelli and myself. We have not found a positive reaction to be universally present in general paresis and almost universally present in tabes, as has been published by so many writers abroad. The presence or absence of the reaction, even in tabes and general paresis, depends more or less on the active luetic virus and less on the terminal cortical or spinal cord changes which are responsible for the symptoms of general paresis or of tabes dorsalis. Our own results in tabes and general paresis have been as shown in the accompanying table.

In this series of 28 cases of tabes, 18, or 64.3 per cent., were positive and 10, or 35.7 per cent., were negative. For the purpose of this table I have considered all weak positive cases of the same value as the more positive ones. This percentage is a little lower than that of some of the former investigators, though it is even a little higher than the statistics of Hoehne,

who found a positive reaction in 60 per cent. of 45 cases of tabes, but he has in his list 12 cases of doubtful tabes in which there was a positive reaction in 41.7 per cent. In our list we have had no doubtful cases of tabes, and I take it that in every neurologic clinic there will surely not be 25 per cent. of doubtful cases of tabes dorsalis as there are in this list, which has been issued from a dermatologic and not a neurologic clinic. Wassermann and Plaut found a positive reaction in 70 per cent. of their tabic patients; others claim as high as 90 per cent., and Nonne apparently obtained a positive reaction in 90 per cent. of the blood examinations and 50 per cent. in the examinations of the spinal fluid. Our own figures are, therefore, in general agreement with those who place the percentage somewhere between 65 and 70 per cent. The character of the patients has much to do with the percentages of the reaction. Of the 28 cases of tabes referred to in this paper, 19 were observed in my private practice, and of these at least half were patients who had been under constant observation over a period varying between three and ten years and all of them had received much treatment. Even before the importance of the Wassermann reaction had been disclosed I had been in the habit of subjecting my tabic patients to a course of sublimate injections at least twice a year. This will account for the fact that of the nine negative cases of tabes in my series seven were cases of patients who had been subjected to this line of treatment. It can, therefore, be seen readily enough that if I were to tabulate only hospital cases and those seen for the first time during the past year the percentage of positive reactions would be very much higher. It is also worthy of note that all the female tabic patients, as well as all the female general paretics, gave a positive reaction. A reaction which was positive in a number of tabic patients before treatment was begun gave a negative reaction after a course of several weeks' treatment had been persisted in.

In spite of these high percentages we can not expect much help from the reaction in those cases of spinal or cerebrospinal lues in which the tabic type predominates, for in both these groups of cases a positive reaction might be obtained and yet no light whatever will be thrown on the spinal character of the morbid changes underlying the symptoms. In every case in which a positive reaction was obtained, specific treatment was pushed with much more energy than would otherwise have been the case.

Among these cases of tabes I wish to single out two for special mention. They have both been under observation for many years, the one during a period of four, the other during a period of ten years at least, and both of these were puzzling for a long period because they presented no other symptom than a dissociation of sensation within the distribution of the fifth nerve, the affection in one case becoming bilateral, in the other remaining unilateral. Both these patients—the one a man of 35, the other of 38 years, the one a merchant and the other a machinist—presented positive reactions. The one patient was observed for years before any other symptoms of tabes were in evidence, but to the dissociated sensation of the trigeminal distribution has now been added a loss of knee-jerks and an ataxic gait, whereas the other still presents no other symptom except a difference in the knee-jerks and some vague and occasional lightning pains. After finding a positive reaction in these two cases, strenuous mercurial treatment was given, always by hypodermatic injections, and strangely enough in both these cases the trigeminal symptoms have been distinctly diminished since the hypodermatic injections were begun, and in both the tabic process seems for the present to have come to a standstill.

Of the 31 cases of general paresis, 32.3 per cent. gave a negative reaction and in 67.7 per cent. the reaction was positive. It will be seen that these percentages are almost identical with those obtained in tabes, whereas other observers have recorded higher percentages. The same explanation that I have given in the cases of tabes will hold to a certain degree for general paresis. All of the cases of general paresis were progressive in their symptoms in spite of the mercurial treatment to which the patients had been subjected. Among the list of cases are several that have lasted a period of two years or more, and all of these cases of old standing gave a negative reaction. Another possible explanation for the low percentages of positive reactions in my cases may be the fact that a number of these cases were in the psychopathic ward of Bellevue Hospital, where patients are retained only over a period of four or five days and where the diagnosis often has to be made hastily, so that there is a bare possibility that some of those which have been classed as cases of general paresis might possibly have belonged to the category of doubtful cases. I have placed in a separate series 7 cases which were unquestionably doubtful ones and of these 7, 5 gave a negative reaction and 2 a positive reaction, one of these 2 positive reactions being weak positive. The contrast between these doubtful cases and undoubtedly genuine cases is striking enough to make us appreciate the value of a positive reaction when it is found, but in the case of general paresis again the finding of a positive reaction does not help us materially in making a differential diagnosis between typical general paresis and syphilitic pseudoparesis. A most interesting example of this character was that of a patient (No. 24) who had had tabes for many years and in addition to these symptoms of tabes had passed through attacks which would ordinarily be classified as manic or manic-depressive attacks, with occasional speech disturbances that were a little like those of general paresis and with occasional delusions of an expansive character. The diagnosis of general paresis was made offhand by a num-

cording to his recent modification, the reactions have tallied in all but four cases. Such discrepancies as have occurred will no doubt be accounted for by greater perfection in the technic of both methods. Noguchi's method appears to be unusually sensitive, and we trust that he will be able to satisfy all of us that a positive Noguchi reaction means active lues, as I am fully persuaded a positive Wassermann reaction does.

I must leave the determination of methods and the description of their imperfections, if there be such, to others. I am concerned in this paper with the relation of the Wassermann reaction to diseases of the central nervous system, and, in order to avoid criticism as to the method employed, Dr. Castelli and myself have adhered closely to the technic of the Wassermann school, as we acquired it in Berlin, and have not deviated from the original method in any particular, except that we have substituted the alcoholic extract of the syphilitic fetal liver for the aqueous extract. This is supposed by some to make the reaction less sensitive. Wassermann himself was opposed to the introduction of the alcoholic extract for a time, but this point, I believe, has now been yielded by him and his followers. At all events, using the alcoholic extract has given us most satisfactory results, as was proved by a large series of tests in which all precautions regarding the necessary controls were employed. It is well known, no doubt, by the majority of those present, that the theory on which the reaction was founded has received rather a serious blow, inasmuch as the inhibition of hemolysis was obtained not only when syphilitic liver extract was used, but also when the extract of normal liver was employed and when other lipoid substances were used.[3] Whatever the explanation of this may prove to be, the fact remains that in an unusually high percentage of cases of syphilitic and parasyphilitic diseases the blood serum, if examined according to Wassermann's directions, gives a very definite inhibition of hemolysis, whereas complete hemolysis ensues in the serum taken from patients who are not afflicted with any syphilitic taint.

The conditions of practice and even of my hospital service have made it necessary to restrict my examinations largely to the examination of the blood serum. No doubt Nonne is correct in insisting that the full truth can be obtained only after a consideration of the cellular elements in the spinal fluid, the globulin content, and the specific reaction of blood and serum and of the spinal fluid. In a small number of the cases (15) the spinal fluid has been examined, and in one case of a child, when it was impossible to obtain sufficient blood for the Wassermann test, a blister was drawn—following the suggestion of Dr. Kaplan to one of my assistants—and serum obtained in this fashion. I wish in this communication to give some of the more important results obtained in a series of about 250 cases. In many of these several tests were made.

All investigators are agreed as to the value of a positive Wassermann reaction. If it signifies anything at all, it indicates a more or less active luetic process somewhere in the system. A negative reaction by common consent does not preclude the presence of syphilis and yet a negative reaction, it seems to me, often gives valuable information. In the vast majority of cases in which the negative reaction is obtained, the thought of syphilis may be dismissed. In a large number of others, however, in which a positive reaction has been found present at the beginning of the disease, and in which a negative reaction has been obtained in the course of or after prolonged treatment, it is only fair to assume that the syphilitic virus has been neutralized as a result of the therapeutic measures employed.[4] In this connection it is important to note that a positive Wassermann reaction may often be wanting in spite of the true syphilitic nature of the disease, if intense or prolonged antisyphilitic medication had been employed before the first test was made. As a matter of routine in my hospital practice the rule had been established that neither mercury nor iodids were to be administered to any patient until the Wassermann test had been done. Assuming, then, that a Wassermann reaction may furnish corroborative evidence as to the presence or absence of an active syphilitic virus, let me give in some detail the results obtained in various groups of cases.

I. IN TABES AND GENERAL PARESIS

As I have intimated before, the reaction is hardly needed as corroborative evidence in these two conditions, because in fully 95 per cent. of the cases the diagnosis can be safely made. The chief difficulties have been experienced in the differential diagnosis, in former years, between tabes dorsalis and syphilitic spinal disease simulating tabes, or between general paresis and specific pseudoparesis. But the Wassermann reaction will be expected to be positive in all of these conditions and can, therefore, throw little light on the exact nature of the morbid process. It may be of some value in those cases in which the differential diagnosis has to be made between general paresis and neurasthenia. The preponderance of opinion would seem to favor the idea that if a Wassermann reaction is positive, the disease is necessarily paresis and not neurasthenia. But if we suppose that the neurasthenic individual has had a preceding syphilitic infection, as well he might have, it would not be fair to infer general paresis merely because the patient gives a positive reaction. And this leads me to the first opinion which I wish to express, as a result of my experience, and that is that a positive Wassermann reaction implies an active luetic process somewhere in the system. Any inference beyond this point seems here hardly to be justifiable. I can in this way account for the discrepancy between the figures published abroad regarding tabes and general paresis and those which have been obtained by Dr. Castelli and myself. We have not found a positive reaction to be universally present in general paresis and almost universally present in tabes, as has been published by so many writers abroad. The presence or absence of the reaction, even in tabes and general paresis, depends more or less on the active luetic virus and less on the terminal cortical or spinal cord changes which are responsible for the symptoms of general paresis or of tabes dorsalis. Our own results in tabes and general paresis have been as shown in the accompanying table.

In this series of 28 cases of tabes, 18, or 64.3 per cent., were positive and 10, or 35.7 per cent., were negative. For the purpose of this table I have considered all weak positive cases of the same value as the more positive ones. This percentage is a little lower than that of some of the former investigators, though it is even a little higher than the statistics of Hoehne,

who found a positive reaction in 60 per cent. of 45 cases of tabes, but he has in his list 12 cases of doubtful tabes in which there was a positive reaction in 41.7 per cent. In our list we have had no doubtful cases of tabes, and I take it that in every neurologic clinic there will surely not be 25 per cent. of doubtful cases of tabes dorsalis as there are in this list, which has been issued from a dermatologic and not a neurologic clinic. Wassermann and Plaut found a positive reaction in 70 per cent. of their tabic patients; others claim as high as 90 per cent., and Nonne apparently obtained a positive reaction in 90 per cent. of the blood examinations and 50 per cent. in the examinations of the spinal fluid. Our own figures are, therefore, in general agreement with those who place the percentage somewhere between 65 and 70 per cent. The character of the patients has much to do with the percentages of the reaction. Of the 28 cases of tabes referred to in this paper, 19 were observed in my private practice, and of these at least half were patients who had been under constant observation over a period varying between three and ten years and all of them had received much treatment. Even before the importance of the Wassermann reaction had been disclosed I had been in the habit of subjecting my tabic patients to a course of sublimate injections at least twice a year. This will account for the fact that of the nine negative cases of tabes in my series seven were cases of patients who had been subjected to this line of treatment. It can, therefore, be seen readily enough that if I were to tabulate only hospital cases and those seen for the first time during the past year the percentage of positive reactions would be very much higher. It is also worthy of note that all the female tabic patients, as well as all the female general paretics, gave a positive reaction. A reaction which was positive in a number of tabic patients before treatment was begun gave a negative reaction after a course of several weeks' treatment had been persisted in.

---

[3] Professor Kopp (München med. Wchnschr., May 11, 1909) has endeavored (I think, in vain) to minimize the universal enthusiasm regarding the clinical value of this method. Since writing the above, Neisser has spoken frankly of its tremendous importance.

[4] Since writing the above, corroboration of this view has come to me in the article of Hoehne (Berl. klin. Wchnschr., May 10, 1909) entitled: Die Wassermann'sche Reaktion und ihre Beeinflussung durch die Therapie.

* Juvenile general paralysis

In spite of these high percentages we can not expect much help from the reaction in those cases of spinal or cerebrospinal lues in which the tabic type predominates, for in both these groups of cases a positive reaction might be obtained and yet no light whatever will be thrown on the spinal character of the morbid changes underlying the symptoms. In every case in which a positive reaction was obtained, specific treatment was pushed with much more energy than would otherwise have been the case.

Among these cases of tabes I wish to single out two for special mention. They have both been under observation for many years, the one during a period of four, the other during a period of ten years at least, and both of these were puzzling for a long period because they presented no other symptom than a dissociation of sensation within the distribution of the fifth nerve, the affection in one case becoming bilateral, in the other remaining unilateral. Both these patients—the one a man of 35, the other of 38 years, the one a merchant and the other a machinist—presented positive reactions. The one patient was observed for years before any other symptoms of tabes were in evidence, but to the dissociated sensation of the trigeminal distribution has now been added a loss of knee-jerks and an ataxic gait, whereas the other still presents no other symptom except a difference in the knee-jerks and some vague and occasional lightning pains. After finding a positive reaction in these two cases, strenuous mercurial treatment was given, always by hypodermatic injections, and strangely enough in both these cases the trigeminal symptoms have been distinctly diminished since the hypodermatic injections were begun, and in both the tabic process seems for the present to have come to a standstill.

Of the 31 cases of general paresis, 32.3 per cent. gave a negative reaction and in 67.7 per cent. the reaction was positive. It will be seen that these percentages are almost identical with those obtained in tabes, whereas other observers have recorded higher percentages. The same explanation that I have given in the cases of tabes will hold to a certain degree for general paresis. All of the cases of general paresis were progressive in their symptoms in spite of the mercurial treatment to which the patients had been subjected. Among the list of cases are several that have lasted a period of two years or more, and all of these cases of old standing gave a negative reaction. Another possible explanation for the low percentages of positive reactions in my cases may be the fact that a number of these cases were in the psychopathic ward of Bellevue Hospital, where patients are retained only over a period of four or five days and where the diagnosis often has to be made hastily, so that there is a bare possibility that some of those which have been classed as cases of general paresis might possibly have belonged to the category of doubtful cases. I have placed in a separate series 7 cases which were unquestionably doubtful ones and of these 7, 5 gave a negative reaction and 2 a positive reaction, one of these 2 positive reactions being weak positive. The contrast between these doubtful cases and undoubtedly genuine cases is striking enough to make us appreciate the value of a positive reaction when it is found, but in the case of general paresis again the finding of a positive reaction does not help us materially in making a differential diagnosis between typical general paresis and syphilitic pseudoparesis. A most interesting example of this character was that of a patient (No. 24) who had had tabes for many years and in addition to these symptoms of tabes had passed through attacks which would ordinarily be classified as manic or manic-depressive attacks, with occasional speech disturbances that were a little like those of general paresis and with occasional delusions of an expansive character. The diagnosis of general paresis was made offhand by a num-

ber of men who had seen the patient and his early death has been freely predicted in each one of the attacks; but, confident of the luetic character of his symptoms and being willing to make a diagnosis of pseudoparesis only and not of the genuine kind, I had predicted his recovery, and he is at present enjoying excellent health, his tabic symptoms being stationary and his mental symptoms for the present being absolutely in abeyance. In this patient the blood examination taken early in January of this year was most positive, and very soon thereafter a violent outbreak occurred. We have not been able to take another reaction since, but the improvement set in as soon as he had been brought under the influence of mercurial treatment. Incidentally it is well to note that there are psychic conditions in tabic patients, and surely in those who have had constitutional syphilis which need not necessarily take the form of general paresis, and this seems to me to be a fact which is often overlooked.

The Wassermann reaction in tabes and in general paresis is of special use only in so far as it tends to corroborate the theory of the specific origin of the two diseases, and also in so far as it gives one good reason to adopt rigid antisyphilitic measures until the character of the reaction has been altered as a result of treatment.

But to pass from tabes and general paresis to other forms of central nervous disease, I will detail briefly some of the experiences of the past year. And here I will refer first to cases in which the diagnosis between disseminated sclerosis and multiple cerebrospinal syphilis was difficult to establish and to another in which it was a question whether the patient was suffering from spinal lues or from amyotrophic lateral sclerosis.

MULTIPLE SCLEROSIS AND MULTIPLE CEREBROSPINAL SYPHILIS

Two patients, both women, one in private practice and the other at the hospital, were under my care. One patient (No. 49) was a woman, 28 years of age, who had been under my treatment a few years ago for a spastic paraplegia with very slight disturbance of the bladder and rectum and slight sensory disturbances involving both lower extremities. There was no involvement of the cranial nerves, her speech was occasionally a little halting, and on extreme moving of the eyes there was a slight nystagmus. There was also a slight ataxic tremor of the upper extremities which might have been interpreted as an intention tremor. At that time a differential diagnosis between multiple sclerosis and multiple cerebrospinal syphilis was not definitely made, although I was inclined to adhere to the suspicion of syphilis in spite of the pupils, which were entirely normal in their reactions. After treatment for a number of months by mercurials chiefly, and some iodids, the patient made a good recovery, and about one year after her dismissal from treatment gave birth to a normal child. In December, 1908, she visited me again complaining of a gradually developing stiffness of the legs; she was able, however, to walk to and from my office and otherwise presented no symptoms. The Wassermann test was made and the reaction was a very positive one. A week later the lower extremities were not only stiff, but distinctly weakened, and from this time on for the following four weeks she experienced great difficulty in getting around. It was not practicable to have her return regularly for injections; she was given large doses of mercury by inunction. After two months distinct improvement set in, she was able to get about again, both the rigidity and the paralysis disappearing. The only thing that was left was a slight unsteadiness in her walk and easy fatigue on exertion. She also complained of numbness in the left hand.

While the recurrence of attacks would have favored the diagnosis of spinal syphilis, it is well known that even in multiple sclerosis such remissions occur, and in this case a positive Wassermann reaction was a great aid in diagnosis.

The other patient (No. 29) is the wife of a physician, whom I have had under treatment off and on for a number of years. She has at various times had transitory attacks of paraplegia, with marked scanning speech and with great increase of the deep reflexes and marked rigidities. The husband is entirely ignorant of any specific infection and was much more inclined to the belief of a disseminated sclerosis than of a specific spinal disease. This patient had been sent to the hospital last year when she had an attack of spastic paraplegia, and after twenty-three injections there was marked improvement, so that she had practically been feeling well during the greater period of the winter. On December 3 of last year, at a time when she had ceased all treatment for a number of months, the Wassermann test was made and the reaction was found to be positive. Following this she was subjected to another course of injections and remained in a tolerable state of health until about a month ago, when she again suddenly became paraplegic, with considerable pains radiating down the limbs, and had again to be sent to the hospital for another course of treatment. Of the specific character of her trouble there can be no doubt.

As a companion-piece to these two patients I might mention another, a young woman, 25 years of age (No. 41), who had while in the hospital a transitory attack of hemiplegia, who presents marked nystagmus, slow, hardly scanning speech, ataxia of the upper extremities, and occasional weakness of the lower extremities, although never so marked that she is compelled to remain in bed or on a chair; but her disease, which I have been able to follow for at least six years, has been characterized by most marked remissions, and, inasmuch as she was a young married woman who had never given birth to children, the differential diagnosis between multiple sclerosis and multiple syphilis was not an easy one to establish. In her case the several tests which were made at varying periods have been negative, and I feel certain that the case will prove to be one of multiple sclerosis and not of syphilis.

The difficulties in diagnosis were quickly cleared up in a hospital case of a woman about 40 years of age who presented marked atrophy of the thenar and hypothenar muscles of both hands, with increase of the reflexes both in the upper and lower extremities. and with some slight involvement of the sphincters and a complete spastic paraplegia of the lower extremities. The disease came on much more suddenly than we are accustomed to see it come on in amyotrophic lateral sclerosis, so that there was some doubt as to whether the case was one of this character or whether it might possibly be a form of cerebrospinal lues. In this case the blood reaction was found positive and the cerebrospinal fluid sent to Dr. Noguchi for examination was reported by him very strongly positive. On the strength of these findings the patient was subjected to marked antiluetic treatment, but she became completely paraplegic, lost control over her bladder and rectum, developed a huge bed-sore and died of the disease within a few weeks. The autopsy revealed a most marked cerebrospinal meningomyelitis specifica. As this was the first one of my series of cases to be examined, it can readily be seen that I was much impressed with the Wassermann test as an aid to diagnosis in doubtful cases.

In addition to these cases, there have been a number of ordinary spastic paraplegias (Nos. 13, 19 and 109). In the first two the reaction was negative and there was no special reason to think that there was any specific element in the case. In the third (No. 109) there were all the ear-marks of syphilitic disease, and an infection years ago was conceded. In this case the blood reaction was positive, and the cerebrospinal fluid also gave a very positive reaction. I make mention of this positive reaction of the cerebrospinal fluid as Nonne and others have failed to get a positive reaction in many of these conditions. Several tests were made of this man; all of them were positive, so that there can hardly be a doubt as to the correctness of the observation. It is well worth adding that in this case lumbar puncture was done at least five times, three times while in the hospital under our own observation, and twice while the patient was at another institution. He experienced so much relief—whether it was subjective or not—from the withdrawal of about 15 c.c. that he asked for repeated lumbar puncture. As no ill effects were observed from this, his wish was granted and he left the hospital very much improved and was ready to resume his work as a motorman.

Let me refer here also to another very remarkable case of cerebrospinal lues (No. 32) that had been under my own care in private practice as well as in the private pavilion in the hospital, with several attacks of hemiplegia and of paraplegia, from each of which the patient —now a man about 33 years of age—had recovered. Last summer this patient was sent to Aix-la-Chapelle and was subjected there to a thorough course of mercurial treatment. He reported to me on October 5, after his return from Aix, when I found him practically well, but for safety's sake continued him on small doses of protiodid of mercury—a drug, by the way, in which my confidence is steadily diminishing. On November 20 of last year he reported at my office, stating that the vision of the right eye appeared blurred. On examination I found a distinct swelling of the nerve and some atrophy. I referred him to Dr. Wiener, who reported that the patient exhibited a distinct specific retinitis and evidences of a retrobulbar neuritis. It was not practicable to give him injections, so he was put on inunctions of mercury. The blood was taken for examination and the reaction was found most positive. After twenty inunctions another test was taken and the reaction was weak positive. After thirty inunctions the reaction was negative and has remained negative since.

There was a further interest in this case, inasmuch as with the improvement in the Wassermann reaction there was also a marked improvement in vision, so that on March 9 I could enter on my records the statement that the patient "reads perfectly with the right eye and all trouble with vision seems to have disappeared." On April 12, however, he developed a weakness in the right leg, reminding him of the condition of the leg during his attack of hemiplegia some years ago. He was at once given another course of treatment, and on May 19 of this year, when he was again seen at my office, he had recovered from the attack of transitory paralysis of the leg, his vision was good, he was able to attend to his work and had practically recovered from this renewed attack of paralysis.

Of all the cases of central syphilitic disease that I have seen this has been the most stubborn, at least of those that showed any tendency to recovery. The Wassermann reaction has been of much aid in the treatment of this patient, and I am so much impressed with its value as an indication of active or inactive lues that I have advised the patient to present himself at least twice a year for a blood examination so as to determine whether or not he needs active antisyphilitic treatment even in the absence of all clinical phenomena.

A case somewhat similar to this (No. 116) was under observation during the winter at the hospital. The patient's chief symptom was a blindness which was suddenly developed, and it was a question whether the blindness was due to a specific disease or possibly to poisoning by wood alcohol. In this case both the blood and the cerebrospinal fluid gave a positive reaction. Under mercurial injections the patient was improved and was finally discharged from the hospital, although his vision had not been completely restored, but he had regained sufficient vision to return to his home. In this case we were well aware that wood alcohol might possibly have caused the condition in a man who had previously been infected with syphilis, but without the positive reaction we would not have had the courage to persist as we did in a prolonged course of mercurial treatment.

IN TUMOR OF THE BRAIN, HEMIPLEGIA AND EPILEPSY

I have no desire to multiply details, but I must refer to the aid rendered by the Wassermann reaction in cases of tumor of the brain or of cerebral conditions in which tumor was suspected. An interesting observation was that on a hospital patient (No. 73) who had had considerable nasal trouble, had been treated by a number of nose specialists in an operative way, and shortly after such a course of treatment developed intense frontal headaches, exquisite tenderness over the frontal bone, slight optic neuritis, without running any considerable fever, except such as might have been accounted for by a slight intercurrent complication. In view of the previous history of nasal trouble and operative interference, it was natural to think of abscess or of a possible intracranial neoplasm or else cerebral lues—a condition which one should never overlook. The patient was under treatment at the time when we were most interested in the Wassermann reaction. The test of blood was taken after he had been in the hospital for a number of weeks, but without specific treatment and a positive reaction was recorded. In view of this—and this was an important matter—every thought of operative interference was abandoned; the man was put on sublimate injections. All his symptoms cleared up and he was discharged, cured, from the hospital after a further stay of about four weeks.

It has become a matter of routine treatment in my service at the hospital to take the Wassermann reaction in all cases of brain tumor before operation is decided on, with a view of eliminating specific cases. I have a record of five such tumor cases in all of which the reactions were negative, and in one of them the reaction of the cerebrospinal fluid was also negative. In a sixth case a positive Wassermann reaction helped us out of a serious diagnostic dilemma. The patient is still in my hospital wards. He is a young man about 25 years of age whose chief symptoms were of a bulbar character; typical bulbar speech, constant drooling from the mouth; rigidity of the neck, intense vertigo, so that the patient had to hold his head inclined to the right, and on any attempt to move it forcibly to the left suffered from intense vertigo. He also exhibited, on looking to the left, a most marked lateral and vertical nystagmus. There was strong suspicion of a tumor either of the cerebellum or in the vicinity of the medulla oblongata, but the only fact that was not in concurrence with this view was the entire absence of optic neuritis; and yet we have all known of the occurrence of cerebellar tumors and of tumors in the vicinity of the foramen magnum, where this growth would have had to be, which are not attended by optic neuritis. The man's condition was becoming rather desperate; he could be fed only by the stomach-tube and seemed to be in great danger of respiratory paralysis, and as a last resort—although I did not think a specific condition probable—a blood test was made which gave a distinctly positive reaction. In view of its proximity to the cerebellum I did not venture to withdraw spinal fluid. As soon as the positive reaction was made out, sublimate injections were given to the patient, and within a week a most astonishing improvement occurred; the patient began to swallow food, the nystagmus was lessened, the vertigo diminished, and he seems now to be on a fair road to recovery; another case in which the Wassermann reaction has proved to be of incalculable value.

In the hemiplegias much assistance was given by the Wassermann test. We neurologists know how much at sea we often have been regarding the nature of an apoplectic attack, and if the onset was such as to give rise to the suspicion of thrombosis, unless the patient were well advanced in years, we have always had to fall back on the theory of a specific endarteritis. I feel that we can depend on the Wassermann reaction to corroborate such a suspicion or to diminish its probability. In the paper which I read before the Association of American Physicians, together with Dr. Collins, on "The Value of the Wassermann Reaction in Cardiac Disease" I reported the case of a hospital patient whose condition was most puzzling. He had a distinct endocarditis affecting both the aortic and the mitral valves. Shortly before entering the hospital he sustained an attack of hemiplegia which was very slow in its mode of onset, entirely without loss of consciousness, and in which the arm and leg were not simultaneously paralyzed. The onset of this did not at all correspond with the theory of embolism due to heart disease. A Wassermann reaction was positive in this patient, and I inferred from this that, although the patient had heart disease, he also had specific endarteritis, and that his attack of hemiplegia was due to thrombosis and not to embolism; another instance, it seems to me, in which the evidence furnished by the Wassermann reaction may be of great diagnostic value.

The Wassermann reaction has been of the greatest help to me in a number of cases of epilepsy in which syphilis was suspected as the only possible cause. Case 128 was one of hereditary lues with epilepsy in which the reaction was positive; and in one case (No. 89), a young man who had acquired syphilis a number of years ago and who gave a positive reaction, had also developed epileptic attacks, the meaning of which was supposed to be in doubt, but with the positive Wassermann reaction I think we need not hesitate to ascribe these spells to brain syphilis.

I have mentioned the cases in which positive reactions have been of great help, but a negative reaction has often been just as instructive, particularly in the case of tumor of the brain, in cases of headaches, and in conditions of disease of the peripheral arteries, more or less resembling Raynaud's disease and erythromelalgia, in which a negative reaction has led me to believe that the suspicion which I once entertained, that these conditions might be of specific origin, can not be defended.

In view of such experiences as I have recorded, I do not hesitate to speak enthusiastically of the value of the Wassermann reaction in neurologic diagnosis. I am certain that within recent years no aid to diagnosis has been given us which can at all equal it in value and in its importance. It should, however, be interpreted merely as a finding corroborating or disproving the suspicion of syphilis, and I would urge that every neurologist acquaint himself personally with the method so that he may learn to employ it and may help to determine by further investigations what the limitations to its usefulness may be, for limitations will surely be found.

I was soon convinced that the Wassermann test was valuable in determining our therapeutic procedures. As a result of my own experiences I would urge that a positive Wassermann reaction is an indication for antisyphilitic treatment; and as regards diseases of the central nervous system, I mean treatment by mercury and preferably by mercurial injections, I have placed reliance on the soluble salts, but I will not differ from those who have a predilection for the insoluble mercurial salts, or who still pin their faith to the iodids. It may be as well, however, to state my conviction that, while I have seen specific headaches and milder specific conditions improve under the administration of iodids, specific myelitis or any serious specific invasion of the cord or brain has, in my opinion, been benefited only by systematic mercurial treatment. These views, which I have held for some time, are, it seems to me, corroborated in the recent interesting statistics of Hoehne, who shows that calomel and sublimate injections appear to be the most efficient. This writer finds that the Wassermann reaction is changed from positive to negative more often after the administration of these two mercurial preparations than after other forms of treatment. If we remember in what haphazard and vague way antisyphilitic treatment has been given for years, both in nervous and in other diseases supposed to be of syphilitic origin, we must welcome a method which gives us some sort of rational basis for our therapeutic procedures. I maintain, therefore, that the Wassermann reaction has a positive value not only as an aid to diagnosis, but also as an aid to treatment.

THE SERODIAGNOSIS OF SYPHILIS *

HIDEYO NOGUCHI, M.D.
Associate Member of the Rockefeller Institute for Medical Research
NEW YORK

It is my essential purpose to present the results of the analysis of 2,406 blood serums by the complement fixation test, using either Wassermann's or my own method of doing the test. Herewith are given six tables, giving in detail the results of the analysis and of a comparative study of 244 cases of known syphilitic or parasyphilitic conditions in which the Wassermann method and mine are contrasted. I shall also point out briefly the main differences between the Wassermann method and my own, referring to the various other modifica-

---

* Read in the Section on Nervous and Mental Diseases of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

tions in passing. For further details consult my article read before the Section on Pathology and Physiology of this Association.

It is important to bear in mind that the main difference between my system and the Wassermann system lies in my use of a known quantity of amboceptor, while in the Wassermann system we meet a difficulty in the fact that human serum may contain anywhere from 0 to 20 units of natural hemolysin (amboceptor) capable of inducing hemolysin of sheep's corpuscles. This introduces an uncertain factor into the interpretation of the results, inasmuch as an excess of anti-sheep amboceptor leads to hemolysis even in the presence of syphilitic antibody. Any system using foreign corpuscles, such as that of Bauer, Hecht, Stern, and Detre, is equally apt to give fallacious results.

Minor differences often of great importance to the individual doing the test are: (1) in my system it is possible to preserve the various reagents, such as antigen, amboceptor, and, if necessary complement, in stable form, dried on filter-paper and then titrated, ready for use; (2) in my system the quantity of blood necessary for the test is very small, only a few drops; inactivation is not necessary and the blood need not be fresh; (3) the ease with which certain of the reagents can be procured is a factor; in my system human corpuscles are used, and the patient's own cells can be utilized. In all the other methods it is necessary to have a fresh supply of corpuscles, sheep's, horse's, etc., always on hand; (4) all the other methods require a complete laboratory, while any laboratory worker can do my test with a very small equipment.

Table 1 contains a summary of the results obtained by my method. The percentage of positive reactions in these cases of syphilis, manifest or latent, compares favorably with the results obtained by different investigators using the Wassermann system.

TABLE 1.—THE RESULTS OBTAINED BY NOGUCHI'S METHOD IN SYPHILIS, PARASYPHILIS, HEREDITARY SYPHILIS AND SUSPECTS

	Number of Cases.	+	%	—	±
Primary Syphilis	70	65=	92.8	4	1
Secondary Syphilis	197	190=	96	5	2
Tertiary Syphilis	177	159=	89.9	16	2
Early Latent Syphilis	115	87=	75.6	24	4
Late Latent Syphilis	150	119=	79.3	27	4
Under Prolonged Treatment	39	4=	10.2	32	3

† This serum was sent to me by Dr. Howard Fox, who failed to obtain another specimen from the same case.

‡ This serum was sent to me by Dr. Schuyler Clark, who made a report on the same case elsewhere.

Table 2 is made up of cases in which syphilis could not be excluded as an etiologic factor. In many cases in which the diagnosis clinically was syphilis, a positive reaction was obtained, and *vice versa*. In the one case of eczema a second specimen was not obtainable; and in this case the patient could not be further interrogated to obtain, if possible, a history of lues. The possibility of hereditary syphilis in the one case of scleroderma could not be excluded; the mother gave a weak reaction to the test.

The material for Table 3 was supplied by Dr. Martin Cohen. In every case in which a positive reaction was obtained, with exception of the one case of acromegaly, the clinical diagnosis made by Dr. Cohen was syphilis.

TABLE 3.—RESULTS OBTAINED BY NOGUCHI'S METHOD IN EYE CASES

	Number of Cases.	+	—	±
Keratitis Interstitialis	12	8	4	0
Iritis (acute)	6	4	2	0
Scleritis	1	0	1	0
Paralysis Exter. Rectus	1	0	1	0
Neuritis Optic	1	1	0	0
Chorioditis Exudative	1	0	1	0
Atrophy Optic	5	0	5	0
Acromegaly with Ocular Symptoms	2	1	1	0
	29	14	15	0

In Table 4 I have reported a number of miscellaneous diseases in which syphilis was probably not a factor. Among these were certain cases of leprosy, malignant neoplasms, tuberculosis, scarlet fever and other exanthemata, in all which diseases positive reactions have been occasionally reported by those using the Wassermann method. It can not be denied that complement is fixed in a large percentage of cases of leprosy; the reasons for this result are as yet unknown. With carcinoma and scarlet fever a positive reaction is rarely obtained. The results here agree closely with those obtained by the Wassermann method.

TABLE 4.—RESULTS OBTAINED BY NOGUCHI'S METHOD IN CASES IN WHICH SYPHILIS CAN BE EXCLUDED WITH A FAIR DEGREE OF CERTAINTY

	Number of Cases.	+	—	±
Leprosy	10	7(!)	2	1
Carcinoma	51	1	48	2

* 1 Carcinoma, 1 Epithelioma, 1 Malaria, 1 Leprosy.

In Table 6 I present the results of the simultaneous examination of 244 cases of known syphilitic conditions by my own and by the Wassermann system. In my opinattempt to move it forcibly to the left suffered from intense vertigo. He also exhibited, on looking to the left, a most marked lateral and vertical nystagmus. There was strong suspicion of a tumor either of the cerebellum or in the vicinity of the medulla oblongata, but the only fact that was not in concurrence with this view was the entire absence of optic neuritis; and yet we have all known of the occurrence of cerebellar tumors and of tumors in the vicinity of the foramen magnum, where this growth would have had to be, which are not attended by optic neuritis. The man's condition was becoming rather desperate; he could be fed only by the stomach-tube and seemed to be in great danger of respiratory paralysis, and as a last resort—although I did not think a specific condition probable—a blood test was made which gave a distinctly positive reaction. In view of its proximity to the cerebellum I did not venture to withdraw spinal fluid. As soon as the positive reaction was made out, sublimate injections were given to the patient, and within a week a most astonishing improvement occurred; the patient began to swallow food, the nystagmus was lessened, the vertigo diminished, and he seems now to be on a fair road to recovery; another case in which the Wassermann reaction has proved to be of incalculable value.

In the hemiplegias much assistance was given by the Wassermann test. We neurologists know how much at sea we often have been regarding the nature of an apoplectic attack, and if the onset was such as to give rise to the suspicion of thrombosis, unless the patient were well advanced in years, we have always had to fall back on the theory of a specific endarteritis. I feel that we can depend on the Wassermann reaction to corroborate such a suspicion or to diminish its probability. In the paper which I read before the Association of American Physicians. together with Dr. Collins, on "The Value of the Wassermann Reaction in Cardiac Disease" I reported the case of a hospital patient whose condition was most puzzling. He had a distinct endocarditis affecting both the aortic and the mitral valves. Shortly before entering the hospital he sustained an attack of hemiplegia which was very slow in its mode of onset, entirely without loss of consciousness, and in which the arm and leg were not simultaneously paralyzed. The onset of this did not at all correspond with the theory of embolism due to heart disease. A Wassermann reaction was positive in this patient, and I inferred from this that, although the patient had heart disease, he also had specific endarteritis, and that his attack of hemiplegia was due to thrombosis and not to embolism; another instance, it seems to me, in which the evidence furnished by the Wassermann reaction may be of great diagnostic value.

The Wassermann reaction has been of the greatest help to me in a number of cases of epilepsy in which syphilis was suspected as the only possible cause. Case 128 was one of hereditary lues with epilepsy in which the reaction was positive; and in one case (No. 89), a young man who had acquired syphilis a number of years ago and who gave a positive reaction, had also developed epileptic attacks, the meaning of which was supposed to be in doubt, but with the positive Wassermann reaction I think we need not hesitate to ascribe these spells to brain syphilis.

I have mentioned the cases in which positive reactions have been of great help, but a negative reaction has often been just as instructive, particularly in the case of tumor of the brain, in cases of headaches, and in conditions of disease of the peripheral arteries, more or less resembling Raynaud's disease and erythromelalgia, in which a negative reaction has led me to believe that the suspicion which I once entertained, that these conditions might be of specific origin, can not be defended.

In view of such experiences as I have recorded, I do not hesitate to speak enthusiastically of the value of the Wassermann reaction in neurologic diagnosis. I am certain that within recent years no aid to diagnosis has been given us which can at all equal it in value and in its importance. It should, however, be interpreted merely as a finding corroborating or disproving the suspicion of syphilis, and I would urge that every neurologist acquaint himself personally with the method so that he may learn to employ it and may help to determine by further investigations what the limitations to its usefulness may be, for limitations will surely be found.

I was soon convinced that the Wassermann test was valuable in determining our therapeutic procedures. As a result of my own experiences I would urge that a positive Wassermann reaction is an indication for antisyphilitic treatment; and as regards diseases of the central nervous system, I mean treatment by mercury and preferably by mercurial injections, I have placed reliance on the soluble salts, but I will not differ from those who have a predilection for the insoluble mercurial salts, or who still pin their faith to the iodids. It may be as well, however, to state my conviction that, while I have seen specific headaches and milder specific conditions improve under the administration of iodids, specific myelitis or any serious specific invasion of the cord or brain has, in my opinion, been benefited only by systematic mercurial treatment. These views, which I have held for some time, are, it seems to me, corroborated in the recent interesting statistics of Hoehne, who shows that calomel and sublimate injections appear to be the most efficient. This writer finds that the Wassermann reaction is changed from positive to negative more often after the administration of these two mercurial preparations than after other forms of treatment. If we remember in what haphazard and vague way antisyphilitic treatment has been given for years, both in nervous and in other diseases supposed to be of syphilitic origin, we must welcome a method which gives us some sort of rational basis for our therapeutic procedures. I maintain, therefore, that the Wassermann reaction has a positive value not only as an aid to diagnosis, but also as an aid to treatment.

In Table 6 I present the results of the simultaneous examination of 244 cases of known syphilitic conditions by my own and by the Wassermann system. In my opinion, they prove conclusively the greater delicacy of my test over the other method in cases of syphilis. This greater percentage of positive reactions is not due to an undue sensitiveness of the method employed by me, but to the elimination in my system of the error introduced by using too great a quantity of amboceptor, as pointed out above.

In conjunction with Dr. J. W. Moore, of the Manhattan State Hospital for the Insane, Ward's Island, New York, I have examined the cerebrospinal fluids of 200 cases of parasyphilitic and other nervous conditions; the results will appear in the July number of the *Journal of Experimental Medicine.*

175 West Seventy-second Street.

THE WASSERMANN REACTION *

E. CASTELLI, M.D.

Consulting Physician at the Columbus Hospital; Instructor of Neurology at the New York Polyclinic; Attending Neurologist at the German Dispensary

NEW YORK

The difference between a normal and a specific serum in the Wassermann reaction is only quantitative, the reaction being provoked by the presence in the blood serum and cerebrospinal fluid of colloidal elements of histogenic and not bacteriogenic origin.

The researches made on the syphilitic serums have proved that the substances to which the syphilitic serums owe their specific property are equally soluble in diluted alcohol. In fact, the alcoholic extracts of the serums contain salts and lipoid substances which either alone or in presence of the extract of liver prevent hemolysis and give a positive reaction. That would prove that the Wassermann reaction is due to the action of lipoid and salts contained in the liver extract on the lipoid and salts contained in the syphilitic serums.

I suppose that if it were possible to make the Wassermann reaction so sensitive that we could thereby detect any trace of colloidal substance contained in the serums to be examined we would have positive reactions in many cases besides the specific ones. When the blood crasis has undergone temporary or permanent modifications, the main necessity, from the clinical standpoint, in the performance of the reaction is to be able to detect the point, above which every positive reaction can be considered specific. To perform, interpret and understand the Wassermann reaction, we must not forget the laws regulating the fixation of complement. The most important is this: If a serum is used containing albuminoid substances in excess, we can have a mechanical fixation of complement. So in the practice of the Wassermann reaction we must remain within the limit of doses in which we are sure no false complement fixation will occur, and in the meantime remain within the dose limit of the hemolytic action, because if we add to the mixture antigen-antibody too strong a dose of complement the complement will not be entirely fixed and the hemolysis of the red sheep corpuscles will take place also if the mixture antigen-antibody has fixed the proper quantity of complement.

Professor Wassermann, in establishing the routine to follow in his method, has been guided entirely by the above-mentioned principle, and his method is of mathematical precision. As I have said, we are in the presence of a quantitative reaction; so admitting and acknowledging the precision of his method, we must come to the conclusion that the only possible fault to be found in his method would be in establishing the basic point of departure for every positive reaction at a level higher than it ought to be, or better not to have made the reaction sensitive enough.

From the clinical standpoint such a feature has no real practical value. The clinician must not forget that no pathologic process ever remains at a standstill. If a specific infection is affecting the blood, and if the Wassermann reaction is efficient enough to detect such a condition, it will detect it some time during its course.

It really does no harm if the condition is detected at the very beginning or shortly after. The Wassermann reaction and quantity of syphilitic antibodies in the serum run along two lines, a coordinate and an abscissa. These two lines must inevitably meet. The crossing point of the abscissa on the coordinate may not coincide exactly with the biologic changes taking place in the blood on account of the infection, but it will certainly occur at a determined moment, during the phase of the infection. When the route and the method followed by the investigator are always the same, the appearance of a positive reaction will represent the saturation of the organism with the same quantity, x, of syphilitic antibodies or colloidal substances, and from that point on every serum examined will always give a positive reaction. From the clinical as well as from the therapeutic standpoint, the reaction meets the exigencies of the clinic almost to perfection. Why should we then modify the method?

Dr. Noguchi, one of the most active Wassermann critics, is entitled to our praise for having spread the knowledge of the Wassermann reaction among many physicians in New York, but I fear he forgot during his pedagogic undertakings that he was training general practitioners and not scientists.

The majority of these physicians learned and applied the Wassermann method after a few days' experience in his laboratory, the majority of them lacking absolutely the elementary scientific foundations necessary to undertaking a work of the importance and delicacy of the Wassermann test; the strict rules established by Wassermann about the dosing, temperature and preparatory operations preceding the test being absolutely neglected. Noguchi's intention of reducing the Wassermann test to the simplicity of a urine analysis for the detection of albumin is very commendable; but can it be realized?

What a difference between his views and those manifested by Fournet before the Paris Board of Health asking that on account of the extreme difficulty and delicacy of the Wassermann test and its invaluable utility to humanity at large, the government should establish laboratories supervised and conducted by competent biologists to do nothing else but the Wassermann test, and to open them free for the practitioners.

The new Noguchi method, the so-called antihuman method, is theoretically rational, though clinically it has sometimes aroused doubt about its efficiency as a substitute for the original Wassermann test. While it is simpler than the original Wassermann, it needs the same amount of care and knowledge in those using it in order to be efficient; so the same criterion and criticism of the original Wassermann prevail for the antihuman method. The Wassermann reaction as it is now has proved to respond perfectly to the demand of the clinic. Noguchi has not proved his to be better; so let us keep what wears better and has the prestige of tradition besides.

---

CEREBROSPINAL FLUID

The real contradictory results have been obtained in the examination and interpretation of the cerebrospinal fluid findings.

I am glad of it, and I think that the time has come for the real understanding of the reaction of the cerebrospinal fluid.

We must understand that there is not always parallelism between blood condition and condition of the spinal fluid in regard to syphilis. In the same way there is no parallelism between the Wassermann reaction and lymphocytosis of the cerebrospinal fluid. Sometimes we have been led astray by considering these two conditions parallel. The reaction of one fluid may be equivalent to the reaction of the other, but not necessarily.

A positive cytodiagnosis of the cerebrospinal fluid and a positive Wassermann reaction of the blood serum can coexist in the same patient as equivalent formulas of the same condition, or can be absolutely independent. Lymphocytosis of the cerebrospinal fluid represents a reaction of defense of the meninges against an invading toxic product. Lymphocytosis is a specific element in meningeal tuberculosis, as it is in meningo-encephalitis, and as it is in tabes and advanced paralysis. But an especially interesting fact from the clinical standpoint is that all skin eruptions have a tendency to produce meningeal reaction, and as a consequence lymphocytosis.

Professor Hutinel gives statistics of seventy-two cases examined, affected by different dermatites, in which the cerebrospinal fluid presented more or less intense lymphocytosis.

I do not doubt that the cerebrospinal fluid in some of these cases, on account of the amount of albuminoid substances contained in it, would have produced a complement fixation. It would have been a mechanical fixation of the complement, masking a real positive Wassermann reaction. This fact is the explanation of the discussion aroused among investigators of the Wassermann test when they have obtained a positive reaction of the spinal fluid in some cases of scarlet fever.

We can find the explanation of this fact, apparently paradoxical, in studying the embryogenesis of tissues and organs.

The meningeal sac and the skin originate from the same layer, "the ectoderm," and it is plausible that these two anatomic elements, physiologically as well as pathologically, are so connected that their clinical manifestations also bear relations of cause and effect. These facts are not uncommon in the clinical observation of clinical phenomena. The so-called polyorrhomenitis, observed first by Semmola, a pathologic condition in which the inflammation of one of the serous membranes of the body is followed by an actual polyserositis, is one of the pathologic symptoms that tend to demonstrate the intimate relation existing between all the endothelial tissues of the body. This is also a phenomenon of embryogenetic origin. Arteriosclerosis can be considered as diffuse fibromatosis invading all the circulatory system.

Admitting this relation between skin and meninges, we can with a very good reason be induced to discard the absolute reliability of the Wassermann test in the spinal fluid as compared to the reaction of the blood serum. I do not mean by that to exclude entirely the spinal fluid from the benefit of the Wassermann test, but I mean that we must restrict the field of value of a positive reaction and probably increase the value of a negative reaction of the cerebrospinal fluid.

GENERAL PARALYSIS

A special value has been attached to the Wassermann test of the spinal fluid as a means of early diagnosis of general paralysis. This conception does not respond to the reality; in fact, I may say that it is in antithesis with it. The number of cases of general paralysis in which the Wassermann reaction gives positive results varies with the different investigators from an average of 50 to 60 per cent. Levaditi says that only 58 per cent. of the cases of general paralysis give a positive Wassermann reaction, but they all establish the fact that the reaction is almost always constant in advanced cases.

So the Wassermann test has much less value than the usual cytodiagnosis of the cerebrospinal fluid for the detection of the early stages of general paralysis, while it is of great usefulness for the prognosis and therapeutics of general paralysis, viz., when in suspected cases of general paralysis the Wassermann reaction of the spinal fluid is negative, the prognosis is more favorable because the specific treatment may help the condition of the patient, either retarding the progress of the disease or bringing on the so-called clinical recovery, viz., a recovery of a few years' duration.

The literature of general paralysis is rich in cases of clinical recovery. Leroy mentions a case of general paralysis in which the process subsided for a period of twelve years.

But when the Wassermann reaction of the spinal fluid in cases of general paralysis is positive we must realize not only that the case is helpless, but that the antisyphilitic treatment is many times dangerous, and will always help a quicker breaking down of the nervous system. So the clinical conclusions to which this information leads are as follows:

1. Positive cytodiagnosis and negative Wassermann reaction of the cerebrospinal fluid constitute a positive sign for the diagnosis of early stages of general paralysis and tabes paralysis, providing that the clinical syndrome accompanying the reaction does not exclude entirely the suspicion of the two above-mentioned pathologic conditions in the organism. Specific treatment is advisable; prognosis hopeful.

2. Positive cytodiagnosis and positive Wassermann reaction of the cerebrospinal fluid constitute a positive sign of the advanced stages of general paralysis, or tabes paralysis, provided that the clinical syndrome confirms our diagnosis. Specific treatment is harmful and sometimes dangerous; prognosis is bad.

Positive cytodiagnosis and positive Wassermann reaction also, if not accompanied by a definite nervous syndrome, constitute an evident sign of the disintegration of the nervous centers.

The reason for these conclusions lies in the fact that we must conceive the genesis of the process producing a Wassermann reaction in the spinal fluid as different in nature from the genesis of the process producing the same in the blood.

One is the process of disintegration of the nervous system; the other shows a process of reaction of the blood. One is a late passive symptom, the other is an early active symptom. The positive reaction in one process is the result of a mechanical fixation of the complement and the other is a normal reaction.

All these statements need explanation, and I am going to give them according to my understanding.

In the early stages of general paralysis the meninges and the nervous centers have not yet entered the phase of reaction, or, better, of defense against the infection, so no presence of antibodies is detectable in the cerebrospinal fluid, while there is predominance of antibodies in the blood serum. In this period the Wassermann reaction will be positive for the blood serum and negative for the cerebrospinal fluid, and the specific treatment will be beneficial, because the encephalus is still in sufficient condition of resistance to stand medication.

In the cases of advanced general paralysis the blood does not produce any more antibodies, while the nervous centers begin to manifest their disintegration, showing the presence in the cerebrospinal fluid of lipoids derived from their albuminoid components. We have in this phase a real autodigestion of the elements of the brain and spinal cord.

During this final phase the specific treatment becomes dangerous because of the impaired resistance of the nervous system to stand medication, and the production of lipoids and albuminoids in the cerebrospinal fluid will be rapid and so much in excess that its examination by the Wassermann test will give positive reaction, because of a mechanical fixation of the complement. This very fact is, in my estimation, of great value, shows that general paralysis is not exactly due to lis or its toxins, but to the immunizing substances duced in our organism which becomes a victim of autointoxication.

This fact would also explain why the spinal fluid of nervous patients with no syphilitic history could give a positive reaction; these are cases of progressive disintegration of the nervous centers, disintegration equal in result to the one produced by syphilis.

This wider interpretation of the reaction increases its value to a very high degree, because it does not state that a syphilitic infection has taken place, but it constitutes an index of the resistance of the nervous system, with the difference that in cases of absence of syphilis the positive reaction will show the passive condition of the nervous tissues, which, exhausted by the reaction against an invading toxin, rapidly proceed to their complete disintegration.

So the clinical interpretation of the Wassermann test will show either active lues when detectable in the blood serum and passive progressive disintegration or the so-called *déchéance* of the nervous system when detected in the cerebrospinal fluid.

This conception of the reaction will change our clinical as well as our therapeutic views, as it will also make us understand why other conditions of the nervous system, like dementia præcox, senile dementia, idiocy, imbecility, etc., could give a positive reaction. That would confirm the idea already expressed by me in the paper read at the opening of the Neurological Society in New York, when I said that probably we would be compelled to give the Wassermann reaction a wider interpretation and consider it in many cases as a grave disturbance of the metabolism of the nervous system, while syphilis would be considered as one of the most important etiologic factors in causing such a condition.

CASES EXAMINED

The statistics of approximately 250 cases examined by me in association with Dr. Sachs show the presence of a positive Wassermann reaction, even in cases in which the syphilitic origin of the disease could not be traced; this indicates the value of the Wassermann reaction in the study of cardiac and vascular diseases.

I shall first mention some of these special cases, inasmuch as the fact of their be
might, in some way, affect the
students in the reliability of the reaction. I shall mention later the results obtained in the examination of patients affected with vascular and cardiac diseases.

The cases apparently non-specific in which the Wassermann reaction was positive are: (1) spontaneous myxedema, (2) scleroderma, (3) lupus, (4) leprosy.

MYXEDEMA

The finding of a positive reaction in a case of spontaneous myxedema may be considered an explanation of the etiology of the disease.

As explained by Hübschman, it is a well-known fact that, in cases of hereditary syphilis, hypertrophy of the thyroid gland is found, with sclerosis of its epithelial tissues and diminution of the colloidal substance. We know that the thyroid gland is a closed gland and that the ductus thyreoglossus, whose exit is in the foramen cecum situated at the base of the tongue, is already obliterated during embryonic life. Thus, a toxic product affecting the gland during embryonic life will remain encapsulated in the thyroid gland and bring within the tissues the degenerative changes of which it is capable. A process of sclerosis, once initiated in the gland, will spread by degrees over all its histologic frame and create a condition of diffuse fibromatosis, because of the tendency of any pathologic process to spread over the surface of tissues of the same type.

The beginning of sclerosis in the epithelial tissue of the gland will create a condition of diffused sclerosis of its epithelial tissue. In the same way, a process of sclerosis beginning in the aorta will gradually bring a condition of fibromatosis of the blood vessels. The effect of the sclerosis of the epithelial tissues on the process of secretion of the thyroid gland will result in a gradual hyposecretion of the colloidal substance due to the changes taking place in the epithelial cubical cells deputed to the secretion of this substance. As soon as the hyposecretion reaches such a degree as to affect the metabolic processes connected with the functions of the thyroid gland the first symptoms of myxedema will appear. Hereditary syphilis might well be considered one of the factors in the production of spontaneous myxedema, *without clashing with the clinical conception* of the obscure etiology of the disease until recently entertained.

SCLERODERMA

I obtained a positive Wassermann reaction in two cases of scleroderma examined and the same results are reported by other investigators. I am inclined to think that ordinary scleroderma, like scleroderma neonatorum and all forms of athrepsia and cachexia, is many times a manifestation of hereditary syphilis. Further investigations of the relation between Wassermann reaction and the different cachexias will probably make clear the obscure etiology of these diseases.

LUPUS

Acquired as well as hereditary syphilis plays a very important rôle in the etiology of tuberculosis. The association of the two diseases in the same subject can assume two forms or types—anatomico-pathologically distinct, but identical from a practical standpoint. In one type we have association of lesions and in the other association of soil.

Association of Lesions.—This is the fusion of two lesions in the same region, and lupus constitutes one of the important characteristic forms of this tuberculoluetic hybridism.

Association of Soil.—This is the result of the simultaneous evolution of the two diseases on the same subject with reciprocity of influence of one disease over the clinical course of the other. We have one of the characteristic types of this association of soil in pulmonary tuberculosis affecting a syphilitic subject. The fact of a positive Wassermann reaction having been found in a case of lupus can be accepted only as a proof of the existence of these forms of syphilo-tuberculous hybridism.

LEPROSY

The positive Wassermann reaction obtained in a case of leprosy finds a plausible explanation in the theory that the case was one of tuberculous leprosy implanted on a syphilitic soil. It would be advisable to make further investigations of associations of this nature to establish whether this form of hybridism could constitute a new factor in the pathology of syphilis.

CARDIAC AND VALVULAR DISEASES

In five cases of aneurism examined—four of the cardiac aorta and one of the innominate—the Wassermann reaction was positive in each. Two of these patients admitted having had syphilis, two denied it, and one had chancroid.

In thirteen cases of the incompetency of the aortic valve, only one gave a negative reaction and two a weak positive. If we consider the weak positive doubtful, 77 per cent. of aortic insufficiency gave a positive reaction. Of these thirteen cases, eight acknowledged a previous syphilitic infection; the other five denied.

In five cases in which both aortic and mitral disease existed, there was one positive, two weakly positive and two negative. In eleven cases of mitral disease only, the Wassermann test was positive and in two cases negative, and in all these cases syphilis was either unknown or denied.

Owing to the fact that a cardiac lesion of syphilitic origin is not to be clinically differentiated from a lesion of another nature, we can easily understand the importance of the Wassermann test in the study of cardiac and vascular diseases.

TREATMENT OF SYPHILIS

My views on treatment in relation to the Wassermann reaction are in accordance with those of others, and are already mentioned in a preceding paper of mine.

The Wassermann reaction, from the point of view of treatment of nervous diseases, has almost inverted our usual therapeutic formulas. All the nervous manifestations of syphilis have been until now observed as postinfectious manifestations; so our intervention with active therapeutic measures has been a postinfection intervention. To-day, now that we have the possibility of detecting the infection during the intrainfectious period, our therapeutics will be intrainfectious and the possibility of avoiding or better preventing the manifestations of syphilis have been achieved to a great extent. So for a repressive therapeusis we have substituted a preventive one; though we must realize that we have only conquered the possibility of a preventive therapeusis, but not its methods.

We are to-day in the condition of the owner of a claim in a gold region before the soil has been exploited and the mine put in working condition.

Everything concerning the therapeutics of syphilis has been restricted to the use of two therapeutic agents, viz., mercury and iodid. Admitting that these two elements act on the system either as antiseptics or as alteratives, it is absurd to think that no other therapeutic elements answering the same purposes exist in the entire Pharmacopeia.

Does mercury act as a specific agent or does it act as a general antiseptic? If the action of mercury on the system should be purely antiseptic, are we not entitled to consider the action on the system of other antiseptics probably less deleterious than mercury? And if its action is an alterative one, are we not entitled to the same privilege?

It is undoubtedly true that a substance capable of producing in people working in mercury mines the classic syndrome of hydrargyrism—principally tremors, paralysis, hysteria, cachexia, etc.—can not help but constitute also a deleterious factor for the organism if given in small repeated doses.

The organic condition produced by a slow but prolonged action on the system of any toxic element is the establishment of pathologic lesions in the organism, functional at first, then anatomic. And we must remember that any pathologic symptom, when allowed to remain, even if purely functional, takes root in the system, and produces anatomic changes in the organs deputed to the manifestations of the symptom. Such an axiom prevails, especially in the pathology of the nervous system, and the consequences are much more serious because the effect spreads over a large surface and involves the organism as a whole. Allow a stimulation of the motor or sensory area to remain long enough, and one will notice that permanent degenerative changes of the morphologic elements situated in the affected area will take place. This continuous overlooking of the fact that a condition of intoxication of the system, when acting for a certain length of time, creates permanent pathologic conditions of the nervous system is one of our main clinical and physiologic misconceptions. Such a statement is proved, for example, by the so-called postoperative neurosis, affecting people that have undergone surgical operations. Many patients have been physical and nervous wrecks after going through operations and very successful ones; this condition is due principally to the absorption of the anesthetic, because of the fact that every chemical element entering the circulatory system acts on the nervous system first, and as a reflex on the entire organism after.

Is the beneficial action of mercury as a therapeutic agent offset by its deleterious action as a metallic poison? It is a question that can not help but puzzle the mind of the clinician. Have we ever tried to answer this question?

While in Munich six years ago I watched closely the experimental work done on the subject in the pathologic institute by a young physician whose name I do not recollect, and whose work never appeared in any of the publications of current medical literature.

One is the process of disintegration of the nervous system; the other shows a process of reaction of the blood. One is a late passive symptom, the other is an early active symptom. The positive reaction in one process is the result of a mechanical fixation of the complement and the other is a normal reaction.

All these statements need explanation, and I am going to give them according to my understanding.

In the early stages of general paralysis the meninges and the nervous centers have not yet entered the phase of reaction, or, better, of defense against the infection, so no presence of antibodies is detectable in the cerebrospinal fluid, while there is predominance of antibodies in the blood serum. In this period the Wassermann reaction will be positive for the blood serum and negative for the cerebrospinal fluid, and the specific treatment will be beneficial, because the encephalus is still in sufficient condition of resistance to stand medication.

In the cases of advanced general paralysis the blood does not produce any more antibodies, while the nervous centers begin to manifest their disintegration, showing the presence in the cerebrospinal fluid of lipoids derived from their albuminoid components. We have in this phase a real autodigestion of the elements of the brain and spinal cord.

During this final phase the specific treatment becomes dangerous because of the impaired resistance of the nervous system to stand medication, and the production of lipoids and albuminoids in the cerebrospinal fluid will be rapid and so much in excess that its examination by the Wassermann test will give positive reaction, because of a mechanical fixation of the complement. This very fact is, in my estimation, of great value, as it shows that general paralysis is not exactly due to syphilis or its toxins, but to the immunizing substances produced in our organism which becomes a victim of autointoxication.

This fact would also explain why the spinal fluid of nervous patients with no syphilitic history could give a positive reaction; these are cases of progressive disintegration of the nervous centers, disintegration equal in result to the one produced by syphilis.

This wider interpretation of the reaction increases its value to a very high degree, because it does not state that a syphilitic infection has taken place, but it constitutes an index of the resistance of the nervous system, with the difference that in cases of absence of syphilis the positive reaction will show the passive condition of the nervous tissues, which, exhausted by the reaction against an invading toxin, rapidly proceed to their complete disintegration.

So the clinical interpretation of the Wassermann test will show either active lues when detectable in the blood serum and passive progressive disintegration or the so-called *déchéance* of the nervous system when detected in the cerebrospinal fluid.

This conception of the reaction will change our clinical as well as our therapeutic views, as it will also make us understand why other conditions of the nervous system, like dementia præcox, senile dementia, idiocy, imbecility, etc., could give a positive reaction. That would confirm the idea already expressed by me in the paper read at the opening of the Neurological Society in New York, when I said that probably we would be compelled to give the Wassermann reaction a wider interpretation and consider it in many cases as a grave disturbance of the metabolism of the nervous system, while syphilis would be considered as one of the most important etiologic factors in causing such a condition.

CASES EXAMINED

The statistics of approximately 250 cases examined by me in association with Dr. Sachs show the presence of a positive Wassermann reaction, even in cases in which the syphilitic origin of the disease could not be traced; this indicates the value of the Wassermann reaction in the study of cardiac and vascular diseases.

I shall first mention some of these special cases, inasmuch as the fact of their being apparently non-luetic might, in some way, affect the belief of the Wassermann students in the reliability of the reaction. I shall mention later the results obtained in the examination of patients affected with vascular and cardiac diseases.

The cases apparently non-specific in which the Wassermann reaction was positive are: (1) spontaneous myxedema, (2) scleroderma, (3) lupus, (4) leprosy.

MYXEDEMA

TREATMENT OF SYPHILIS

My views on treatment in relation to the Wassermann reaction are in accordance with those of others, and are already mentioned in a preceding paper of mine.

The Wassermann reaction, from the point of view of treatment of nervous diseases, has almost inverted our usual therapeutic formulas. All the nervous manifestations of syphilis have been until now observed as postinfectious manifestations; so our intervention with active therapeutic measures has been a postinfection intervention. To-day, now that we have the possibility of detecting the infection during the intrainfectious period, our therapeutics will be intrainfectious and the possibility of avoiding or better preventing the manifestations of syphilis have been achieved to a great extent. So for a repressive therapeusis we have substituted a preventive one; though we must realize that we have only conquered the possibility of a preventive therapeusis, but not its methods.

We are to-day in the condition of the owner of a claim in a gold region before the soil has been exploited and the mine put in working condition.

Everything concerning the therapeutics of syphilis has been restricted to the use of two therapeutic agents, viz., mercury and iodid. Admitting that these two elements act on the system either as antiseptics or as alteratives, it is absurd to think that no other therapeutic elements answering the same purposes exist in the entire Pharmacopeia.

Does mercury act as a specific agent or does it act as a general antiseptic? If the action of mercury on the system should be purely antiseptic, are we not entitled to consider the action on the system of other antiseptics probably less deleterious than mercury? And if its action is an alterative one, are we not entitled to the same privilege?

It is undoubtedly true that a substance capable of producing in people working in mercury mines the classic syndrome of hydrargyrism—principally tremors, paralysis, hysteria, cachexia, etc.—can not help but constitute also a deleterious factor for the organism if given in small repeated doses.

The organic condition produced by a slow but prolonged action on the system of any toxic element is the establishment of pathologic lesions in the organism, functional at first, then anatomic. And we must remember that any pathologic symptom, when allowed to remain, even if purely functional, takes root in the system, and produces anatomic changes in the organs deputed to the manifestations of the symptom. Such an axiom prevails, especially in the pathology of the nervous system, and the consequences are much more serious because the effect spreads over a large surface and involves the organism as a whole. Allow a stimulation of the motor or sensory area to remain long enough, and one will notice that permanent degenerative changes of the morphologic elements situated in the affected area will take place. This continuous overlooking of the fact that a condition of intoxication of the system, when acting for a certain length of time, creates permanent pathologic conditions of the nervous system is one of our main clinical and physiologic misconceptions. Such a statement is proved, for example, by the so-called postoperative neurosis, affecting people that have undergone surgical operations. Many patients have been physical and nervous wrecks after going through operations and very successful ones; this condition is due principally to the absorption of the anesthetic, because of the fact that every chemical element entering the circulatory system acts on the nervous system first, and as a reflex on the entire organism after.

Is the beneficial action of mercury as a therapeutic agent offset by its deleterious action as a metallic poison? It is a question that can not help but puzzle the mind of the clinician. Have we ever tried to answer this question?

While in Munich six years ago I watched closely the experimental work done on the subject in the pathologic institute by a young physician whose name I do not recollect, and whose work never appeared in any of the publications of current medical literature.

One is the *process of disintegration* of the nervous system; the other shows a *process of reaction* of the blood. One is a late passive symptom, the other is an early active symptom. The positive *reaction* in one process is the result of a mechanical fixation of the complement and the other is a normal reaction.

All these statements need explanation, and I am going to give them according to my understanding.

In the early stages of general paralysis the meninges and the nervous centers have not yet entered the phase of reaction, or, better, of defense against the infection, so no presence of antibodies is detectable in the cerebrospinal fluid, while there is predominance of antibodies in the blood serum. In this period the Wassermann reaction will be positive for the blood serum and negative for the cerebrospinal fluid, and the specific treatment will be beneficial, because the encephalus is still in sufficient condition of resistance to stand medication.

In *the cases of advanced general paralysis* the blood does not produce any more antibodies, while the nervous centers begin to manifest their disintegration, showing the presence in the cerebrospinal fluid of lipoids derived from their albuminoid components. We have in this phase a real autodigestion of the elements of the brain and spinal cord.

During this final phase the specific treatment becomes dangerous because of the impaired resistance of the nervous system to stand medication, and the production of lipoids and albuminoids in the cerebrospinal fluid will be rapid and so much in excess that its examination by the Wassermann test will give positive reaction, *because of a mechanical fixation* of the complement. This very fact is, in my estimation, of great value, as it shows that general paralysis is not exactly due to syphilis or its toxins, but to the immunizing substances produced in our organism which becomes a victim of autointoxication.

This fact would also explain why the spinal fluid of nervous patients with no syphilitic history could give a positive reaction; these are cases of progressive disintegration of the nervous centers, disintegration equal in result to the one produced by syphilis.

This wider interpretation of the reaction increases its value to a very high degree, because it does not state that a syphilitic *infection has taken place*, but it constitutes an index of the resistance of the nervous system, with the difference that in cases of absence of syphilis the positive reaction will show the passive condition of the nervous tissues, which, exhausted by the reaction against an invading toxin, rapidly proceed to their complete disintegration.

So the clinical interpretation of the Wassermann test *will show* either *active lues when detectable* in the blood serum and passive progressive disintegration or the so-called *déchéance* of the nervous system when detected in the cerebrospinal fluid.

This conception of the reaction will change our clinical as well as *our therapeutic* views, as it will also make us understand why other conditions of the nervous system, like dementia præcox, senile dementia, idiocy, imbecility, etc., could give a positive reaction. That would confirm the idea already expressed by me in the paper read at the opening of the Neurological Society in New York, when I said that probably we would be compelled to give the Wassermann reaction a wider interpretation and consider it in many cases as a grave *disturbance of* the metabolism of the nervous system, while syphilis would be *considered as one of the most important* etiologic factors in causing such a condition.

CASES EXAMINED

The statistics of approximately 250 cases examined by me in association with Dr. Sachs show the presence of a positive Wassermann reaction, even in cases in which the syphilitic origin of the disease could not be traced; *this indicates* the value of the Wassermann reaction in the study of cardiac and vascular diseases.

I shall first mention some of these special cases, inasmuch as the fact of their being apparently non-luetic might, in some way, affect the belief of the Wassermann *students in the reliability of the reaction. I shall mention* later the results obtained in the examination of patients affected with vascular and cardiac diseases.

The cases apparently non-specific in which the Wassermann reaction was positive are: (1) spontaneous myxedema, (2) scleroderma, (3) lupus, (4) leprosy.

MYXEDEMA

The finding of a positive reaction in a case of spontaneous myxedema may be considered an explanation of the etiology of the disease.

As explained by Hübschman, it is a well-known fact that, in cases of hereditary syphilis, hypertrophy of the thyroid *gland* is found, with sclerosis *of its epithelial* tissues and diminution of the colloidal substance. We know that the thyroid gland is a closed gland and that the ductus thyreoglossus, whose exit is in the foramen cecum situated at the base of the tongue, is already obliterated during embryonic life. Thus, a toxic product affecting the gland during embryonic life will remain encapsulated in the thyroid gland and bring within the tissues *the degenerative changes* of which it is capable. A process of sclerosis, once initiated in the gland, will spread by degrees over all its histologic frame and create a condition of diffuse fibromatosis, because of the tendency of any pathologic process to spread over the surface of tissues of the same type.

The beginning of sclerosis in the epithelial tissue of the gland will create a condition of diffused sclerosis of its epithelial tissue. In the same way, a process of sclerosis beginning in the aorta will gradually bring a condition of fibromatosis of the blood vessels. The effect of the sclerosis of the epithelial tissues on the process of secretion of the thyroid gland will result in a gradual hyposecretion of the colloidal substance due to the changes taking place in the epithelial cubical cells deputed to the secretion of this substance. As soon as the hyposecretion reaches such a degree as to affect the metabolic processes connected with the functions of the thyroid gland the first symptoms of myxedema will appear. Hereditary syphilis might well be considered one of the factors in the production of spontaneous myxedema, without clashing with the clinical conception of the obscure etiology of the disease until recently entertained.

SCLERODERMA

I obtained a positive Wassermann reaction in two cases of scleroderma examined and the same results are reported by other investigators. I am inclined to think that ordinary scleroderma, like scleroderma neonatorum and all *forms of athrepsia and cachexia, is many times* a manifestation of hereditary syphilis. Further investigations of the relation between Wassermann reaction and the different cachexias *will probably* make clear the obscure etiology of these diseases.

LUPUS

Acquired as well as hereditary syphilis plays a very important rôle in the etiology of tuberculosis. The association of the two diseases in the same subject can assume two forms or types—anatomico-pathologically distinct, but identical from a practical standpoint. In one type we have association of lesions and in the other association of soil.

Association of Lesions.—This is the fusion of two lesions in the same region, and lupus constitutes one of the important characteristic forms of this tuberculoluetic hybridism.

Association of Soil.—This is the result of the simultaneous evolution of the two diseases on the same subject with reciprocity of influence of one disease over the clinical course of the other. We have one of the characteristic types of this association of soil in pulmonary tuberculosis affecting a syphilitic subject. The fact of a positive Wassermann reaction having been found in a case of lupus can be accepted only as a proof of the existence of these forms of syphilo-tuberculous hybridism.

LEPROSY

The positive Wassermann reaction obtained in a case of leprosy finds a plausible explanation in the theory that the case was one of tuberculous leprosy implanted on a syphilitic soil. It would be advisable to make further investigations of associations of this nature to establish whether this form of hybridism could constitute a new factor in the pathology of syphilis.

CARDIAC AND VALVULAR DISEASES

In five cases of aneurism examined—four of the cardiac aorta and one of the innominate—the Wassermann reaction was positive in each. Two of these patients admitted having had syphilis, two denied it, and one had chancroid.

In thirteen cases of the incompetency of the aortic valve, only one gave a negative reaction and two a weak positive. If we consider the weak positive doubtful, 77 per cent. of aortic insufficiency gave a positive reaction. Of these thirteen cases, eight acknowledged a previous syphilitic infection; the other five denied.

In five cases in which both aortic and mitral disease existed, there was one positive, two weakly positive and two negative. In eleven cases of mitral disease only, the Wassermann test was positive and in two cases negative, and in all these cases syphilis was either unknown or denied.

Owing to the fact that a cardiac lesion of syphilitic origin is not to be clinically differentiated from a lesion of another nature, we can easily understand the importance of the Wassermann test in the study of cardiac and vascular diseases.

TREATMENT OF SYPHILIS

My views on treatment in relation to the Wassermann reaction are in accordance with those of others, and are already mentioned in a preceding paper of mine.

The Wassermann reaction, from the point of view of treatment of nervous diseases, has almost inverted our usual therapeutic formulas. All the nervous manifestations of syphilis have been until now observed as postinfectious manifestations; so our intervention with active therapeutic measures has been a postinfection intervention. To-day, now that we have the possibility of detecting the infection during the intrainfectious period, our therapeutics will be intrainfectious and the possibility of avoiding or better preventing the manifestations of syphilis have been achieved to a great extent. So for a repressive therapeusis we have substituted a preventive one; though we must realize that we have only conquered the possibility of a preventive therapeusis, but not its methods.

We are to-day in the condition of the owner of a claim in a gold region before the soil has been exploited and the mine put in working condition.

Everything concerning the therapeutics of syphilis has been restricted to the use of two therapeutic agents, viz., mercury and iodid. Admitting that these two elements act on the system either as antiseptics or as alteratives, it is absurd to think that no other therapeutic elements answering the same purposes exist in the entire Pharmacopeia.

Does mercury act as a specific agent or does it act as a general antiseptic? If the action of mercury on the system should be purely antiseptic, are we not entitled to consider the action on the system of other antiseptics probably less deleterious than mercury? And if its action is an alterative one, are we not entitled to the same privilege?

It is undoubtedly true that a substance capable of producing in people working in mercury mines the classic syndrome of hydrargyrism—principally tremors, paralysis, hysteria, cachexia, etc.—can not help but constitute also a deleterious factor for the organism if given in small repeated doses.

The organic condition produced by a slow but prolonged action on the system of any toxic element is the establishment of pathologic lesions in the organism, functional at first, then anatomic. And we must remember that any pathologic symptom, when allowed to remain, even if purely functional, takes root in the system, and produces anatomic changes in the organs deputed to the manifestations of the symptom. Such an axiom prevails, especially in the pathology of the nervous system, and the consequences are much more serious because the effect spreads over a large surface and involves the organism as a whole. Allow a stimulation of the motor or sensory area to remain long enough, and one will notice that permanent degenerative changes of the morphologic elements situated in the affected area will take place. This continuous overlooking of the fact that a condition of intoxication of the system, when acting for a certain length of time, creates permanent pathologic conditions of the nervous system is one of our main clinical and physiologic misconceptions. Such a statement is proved, for example, by the so-called postoperative neurosis, affecting people that have undergone surgical operations. Many patients have been physical and nervous wrecks after going through operations and very successful ones; this condition is due principally to the absorption of the anesthetic, because of the fact that every chemical element entering the circulatory system acts on the nervous system first, and as a reflex on the entire organism after.

Is the beneficial action of mercury as a therapeutic agent offset by its deleterious action as a metallic poison? It is a question that can not help but puzzle the mind of the clinician. Have we ever tried to answer this question?

While in Munich six years ago I watched closely the experimental work done on the subject in the pathologic institute by a young physician whose name I do not recollect, and whose work never appeared in any of the publications of current medical literature.

He had injected into rabbits at different intervals solutions of bichlorid of mercury in varying strength during the period of four months. The spinal cord of these rabbits examined after the period of four months had elapsed showed sclerotic alterations of the posterior column and different in intensity in the different rabbits, but anatomically identical with those of tabes in man.

If this fact does not prove that tabes is caused by the action of a metallic poison, it certainly implies that once the anatomic lesions of tabes are established the advisability of treating a patient with mercury must be taken *cum grano salis,* and the question of using a therapeutic minimal must be the main consideration, if we have to use mercury, because its action in cumulative doses is apt to create anatomic lesions of the spinal cord and act on it as the syphilitic virus does. This also proves that the etiology of tabes is a neurotoxic one, and that other elements besides syphilis might perhaps show a predilection for the spinal cord, and produce a tabetic syndrome.

The question of therapeutics in general has always been neglected and many of us have assumed a rather cynical attitude toward any therapeutic method adopted, attempted or even suggested. I feel altogether differently on the subject, and my earnest belief is that through therapeutics only will medicine achieve the highest degree of evolution. I think that a misunderstanding, or rather a misconception, is at the bottom of our therapeutic failures. My viewpoint in the genesis of diseases is that blood is the bearer and transmitter of any infectious element, and that the localization of the infectious element in a special region or organ of the body is a simple process of metastasis. The microbes and toxins are transported by the blood current to such regions of the body as offer conditions most suitable for the accomplishment of their reactive processes, just as in a similar manner cancer cells are transported to those parts of the body wherein the malignant growths may be reproduced.

Such being the case, its logical consequence is that, if the therapeutic agent should follow the same route as that followed by the infective element, its action, general and local, would take effect as such points presented as are necessary for its action. The therapeutic agent must then be introduced directly into the blood in order to be carried to the place where the source of infection is—the blood must become the clinical recipient of therapeutic elements.

The main problem to solve, then, will be the one concerning the selection of the therapeutic agent in each pathologic condition and its dose. My attempts in this direction have been as many as were permitted by the clinical material occasionally at my disposal; and in order to remain on the subject I shall mention two of the attempts made by me in the treatment of syphilis. In both I was guided by the different clinical views that we could be allowed to assume in regard to the genesis of the infection without failing in logic and altering our conception of its pathogenesis.

If we consider syphilis as a chronic spirillosis in which the pathogenic agent enters the blood current and determines a general infection, we might also see a certain analogy between the *Treponema pallidum* and the plasmodium of malaria. Both enter the blood stream and both can produce severe anemias. This, I think, is the criterion that guided Dr. Benzman of the Diakonenkrankenhaus in Duisbourg in treating syphilis with intravenous injections of chlorohydrate of quinin. I adopted his views in three cases, one of malignant syphilis in which the patient proved to be mercury-immune, having been refractory to mercurial treatment, and in two cases of secondary syphilitic manifestations appearing in two patients that had been previously treated with mercury. All three answered promptly to the treatment. I injected about 4 gm. in the space of twenty days, injecting about 40 cg. each time every other day in the venæ medianæ. The examination of the blood serum by the Wassermann test was not made because the trial precedes the adoption of the Wassermann reaction as mean of diagnosis.

To a second attempt I was guided by considerations of altogether different nature. My earnest conviction, dating many years back, and proved by my paper on the treatment of appendicitis presented at the twelfth annual meeting of the Association of Military Surgeons of the United States in Boston, is that the therapeutic equation to be resolved in medicine is the same as that resolved by surgery, with the difference that for the term "local antisepsis" we must substitute the term "general antisepsis," or, in other words, disease is a closed wound in which the colonization of microbes and the action of toxins accomplish their destructive work far beyond our control. The main difficulty in adopting internal antisepsis is to use a therapeutic agent which is a powerful general antiseptic without being detrimental to the system. I have selected for the purpose, not only in syphilis but in many other infective conditions, a preparation of electric silver, in the colloidal state. The colloidal state of a metal represents a state of extreme division of the metal, an ultramicroscopic suspension of metallic parts in a menstruum. This extreme division corresponds to an immense surface of contact of the metallic substance, and, the substance being antiseptic, to an immense antiseptic area. It has been calculated that the total surface of 1 c.c. of electric gold in the colloid state corresponds to the surface of 600 square meters. This explains the immense antiseptic value of the electric metals in the colloidal state. The action of the electric silver in two cases of tertiary syphilis treated seems to benefit, though in a less degree than does hydrargyrum, the course of the manifestation.

The examination of the blood serum by the Wassermann test before beginning the experiment was strongly positive; the test made after five injections of 3 c.c. gave a weak positive reaction.

I shall follow the cases in order to see if the duration of the antiseptic action of the silver on the system will be such as to consider its action similar to the action of hydrargyrum on the syphilitic virus. If this should be the result, the natural deduction would be that mercury in syphilis does not act as a specific agent, but as an antiseptic one. All these attempts, if repeated on a large scale, would without doubt bring some useful and tangible results in the field of therapeutics. I think that the knowledge of serodiagnosis in different diseases will modify our views in therapeutics and will stimulate a new spirit of research in the different investigators.

CONCLUSIONS

Wassermann has initiated us in the conviction that the study of the chemical and biologic conditions of the blood can be used as methods of clinical diagnosis, and has opened a new era to medicine. It is by working on the development of this new idea that medicine will achieve the results never obtained before, and it is with this fact in view that the minds of the young generation of medical students must be occupied. The evolution of medicine has been relatively slow, because of the irrational methods adopted in clinical studies. A normal condition of the blood implies a normal equilibrium, while an abnormal condition implies a lack of equilibrium of all our systemic functions.

It is rational to think that each pathologic condition must reflect itself in the condition of the blood. It is a pathologic axiom that rationalism confirms, although science has not completely proved it, and to the student of nervous diseases this knowledge must be of more value than to any one else, because it is the nervous system that is the first affected by a condition of dyscrasia.

The nervous system and the circulatory system preside over the harmonization of all individual lives. One harmonizes the functions of the various organs, the other harmonizes their processes of nutrition. These two systems are in direct relation, physiologically and pathologically, and so much so that we can say that the etiology of nervous diseases must principally be found in the pathology of blood, and that the diseases of the circulatory system can find their principal etiologic factors in the conditions of the nervous system.

The Berlin Faculty of Medicine was the first to establish a chair for the teaching of serodiagnosis. It is only a beginning, but, remaining as it is, it will not be the bearer of the many useful results of which it could be capable.

In my opinion, the study of serodiagnosis in particular and of hematology in general must leave the fields of pure biology and enter entirely the field of the clinic.

The utility of the laboratory scientist ceases the moment at which the work of the clinician begins. The scientist will become a real prominent and substantial factor in the progress of medicine when his work goes *pari passu* with the work of the clinician. The medical scientist is always a poor observer of clinical facts, and his clinical deductions are general paradoxes from the practical clinical standpoint; so we can not allow him to draw conclusions of clinical value. We must take his knowledge, his experience and apply it at the bedside. Hundreds of times we shall be compelled to modify and rectify not only his views, but his very method of research in order to harmonize them with our clinical needs, and principally with the views of logical therapeutics.

If every pathologic condition of the organism is the expression of chemical, morphologic or bacteriologic blood formulas and if the principal genesis of disease is found in the changing of the blood conditions, our therapeutic methods also must change entirely, and the therapeutic equation to be solved for each pathologic condition will be to find the therapeutic agent which, introduced directly into the blood, will neutralize that heterogeneous toxic element in circulation which causes the disease.

Hypodermoclysis, venoclysis, seroclysis, etc., will entirely supersede every other therapeutic means.

What is the value of any scientific clinical investigation if in the field of therapeutics we are almost on the same level with Galenus? Do we expect the Rockefeller and Pasteur institutes or any other institution for biologic research to investigate for us the most appropriate method of therapeutics? Every one of our teaching institutions of our hospitals must undertake the colossal task imposed on us by modern exigencies.

We have in Washington squads of healthy human beings used once in a while by the Board of Agriculture in order to investigate the effects on the system of certain chemical ingredients used as food preservers. Many times these squads of white slaves are taken sick or after a certain period of time the functions of metabolism are sufficiently altered to prove that a certain chemical element used in the preservation of food material is of prejudice to health.

Why should we not in all of our institutions with more vital reason do a much more useful and humane thing by having a ward well conducted and equipped with sick patients reserved for therapeutic research?

The division of labor is a principle of economy applicable to medical work as well as to any branch of human activity. Thousands of institutions devoting time and work to the same object, viz., research on rational therapeutics, would bring in a short time the results that thousand of years of ill-conducted, ill-divided and unproperly understood work have been unable to produce. We certainly have no reason to be proud of ourselves to-day. It is enough to watch the throngs of uncultured, unscrupulously absurd and daring healers infecting and infesting public opinion to understand that we are deficient in value and professional prestige. We must work and work intelligently in order to rescue ourselves and our mission.

It is following this order of ideas and ideals that the modern evolution of medicine will achieve its climax; and those who enjoy life in this country, which is a leader of civilization, should show to the entire world that in the fields of medical science we are also striving for a well-earned supremacy.

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. SACHS, NONNE,* NOGUCHI, AND CASTELLI

DR. WILLIAM J. BUTLER, Chicago: I am afraid if we were unacquainted with the literature of this subject we would consider that we were dealing with a new reaction in the Noguchi modification. But, of course, we are still dealing with the Wassermann reaction, founded on the complement-binding principle of Bordet, and we are also dealing with a modification by Noguchi along lines already published by Tschernogubow, who was the first to suggest the use of the anti-human amboceptor, and a simplified system for performing the reaction. But we certainly owe a distinct debt to Noguchi for demonstrating, as he has, that the materials dried on filter paper will retain their properties indefinitely, because we know the great difficulties attendant on the performance of this reaction by virtue of the inconstancy of some of the materials, viz., the antigen and likewise the amboceptor, which may vary decidedly from time to time. If these materials do hold indefinitely in the dried state, it will be a distinct aid to all those who have performed or are performing this reaction, and will undoubtedly extend its application or performance by a number of laboratory workers. I doubt, however, if the general practitioner will ever be able to utilize this test to any advantage, because no one who has not had some training in serological technic could be expected to use any reaction based on this principle and rely on his results, because there are so many possible sources of error irrespective of what modification may be used, and this modification will not be of any great service to such practitioners.

It is generally conceded, I think, that the Wassermann reaction offers a certain diagnosis for syphilis, and I believe that it is likewise found in a few other infections—sleeping sickness, leprosy, and some cases of scarlet fever. I found it in four out of twenty of the latter, and also found it in two cases of noma, also in isolated instances in the presence of

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. SACHS, NONNE,* NOGUCHI, AND CASTELLI

DR. WILLIAM J. BUTLER, Chicago: I am afraid if we were unacquainted with the literature of this subject we would consider that we were dealing with a new reaction in the Noguchi modification. But, of course, we are still dealing with the Wassermann reaction, founded on the complement-binding principle of Bordet, and we are also dealing with a modification by Noguchi along lines already published by Tschernogubow, who was the first to suggest the use of the anti-human amboceptor, and a simplified system for performing the reaction. But we certainly owe a distinct debt to Noguchi for demonstrating, as he has, that the materials dried on filter paper will retain their properties indefinitely, because we know the great difficulties attendant on the performance of this reaction by virtue of the inconstancy of some of the materials, viz., the antigen and likewise the amboceptor, which may vary decidedly from time to time. If these materials do hold indefinitely in the dried state, it will be a distinct aid to all those who have performed or are performing this reaction, and will undoubtedly extend its application or performance by a number of laboratory workers. I doubt, however, if the general practitioner will ever be able to utilize this test to any advantage, because no one who has not had some training in serological technic could be expected to use any reaction based on this principle and rely on his results, because there are so many possible sources of error irrespective of what modification may be used, and this modification will not be of any great service to such practitioners.

It is generally conceded, I think, that the Wassermann reaction offers a certain diagnosis for syphilis, and I believe that it is likewise found in a few other infections—sleeping sickness, leprosy, and some cases of scarlet fever. I found it in four out of twenty of the latter, and also found it in two cases of noma, also in isolated instances in the presence of other infections, but that is only to be expected, because in the many cases that are examined it is certainly reasonable to conclude that the isloated instances of cancer or tuberculosis in which the Wassermann reaction is found, the patients have had syphilis. The evidence seems to show conclusively that the Wassermann reaction means active syphilis, which point has been reiterated by Dr. Sachs, and it is to be looked upon not as a reaction for tabes exactly, nor for paresis, when we are dealing with such cases, but as a reaction for active syphilis.

---

* The paper by Dr. Nonne appeared in THE JOURNAL July 24.

Now, as to why we do not find a positive reaction in all cases of tabes, or, at least, in the vast majority, like we do in paresis, we may theorize from various standpoints. It is conceivable, for instance, that in a condition so chronic as tabes, caused undoubtedly by syphilis in at least the vast majority of cases, and I believe in all, the primary specific infection may have periods of quiescence, when the reaction for syphilis will not be positive. Moreover, such patients are so frequently subjected to specific treatment which has such a powerful influence on the Wassermann reaction, that it is evident we may expect to find frequently negative reactions in tabes. Likewise, with reference to the results with spinal fluid, which have been unusually low in Dr. Nonne's experiments, in comparison to the results with serum, I think that we would also indulge in fantastical excursions into the theoretical side of the question if we attempt to explain it. Dr. Castelli has shown us what ideas one may formulate on the subject. The fact remains, however, that the most practical side of the question is to examine the blood serum, and in a majority of the cases of paresis, and in a large percentage of the cases of tabes, we get a positive reaction with the Wassermann test, thus clinching the etiologic relation to syphilis. I have not had the opportunity to investigate Nonne's butyric acid reaction, but have Noguchi's ammonium sulphate, and I find it, in inflammatory conditions of the meninges, positive; for instance, in the epidemic form of cerebrospinal meningitis; while it is theoretically interesting and possibly might be regarded as an addition to our resources in a diagnostic way, it can not be regarded of specific value.

Dr. Frank E. Fox, Fulton, N. Y.: I agree that Dr. Noguchi's test is not suitable for the general practitioner, but I do not think that Dr. Noguchi really intends this test to be used by the general practitioner, but intends it to be used by men in clinical laboratories and not by men who do two or three tests only, but by men who do a considerable number of tests. I recently read a paper on the comparison of the Wassermann and Noguchi tests in 200 cases, mostly of syphilis in various stages, and the practical results that I have obtained show a larger proportion of positive results from the Noguchi test than from the Wassermann, although at the same time I should say that the two tests run roughly parallel. Of the eight different methods that have been suggested for serodiagnosis of syphilis depending on the principle of complement fixation, all except the method of Noguchi have more or less serious objections.

With regard to one or two difficulties experienced in the practical working of the Wassermann test, I certainly think that the chief difficulty to be encountered is in the preparation of a suitable antigen. If we could have a uniform and standard antigen a great advance would be made. Dr. Sachs has suggested that certain mixtures called A and B, respectively, be used; and it is claimed that the results with the use of these mixtures are practically the same as obtained when the alcoholic extract of syphilitic fetus is used; although they admit that a less number of positive reactions is obtained by these mixtures. Facini states that with mixture B he obtained practically no good results at all and that with mixture A he obtained 66 per cent. + as against 84 per cent. + by using the alcoholic extract of syphilitic fetus.

The one important thing in making a test from a diagnostic standpoint is to repeat the test possibly for two or three weeks in succession, and it is absolutely important to use two or three different kinds of antigen. I think the experience of most observers is that with some extracts positive results are obtained and with others negative; and this should teach us that in an important case for diagnosis two or three different extracts should be used in addition to repeating the dose.

Dr. Alexander S. Wolf, St. Louis: I am a dermatologist and come as a visitor to this symposium. I am especially interested in the importance of the Wassermann reaction for syphilis in cases of obscure nervous diseases. I think something should be said from the standpoint of the dermatologist, when the question of importance and reliability of Wassermann reaction is being discussed. I had an opportunity to review the recent literature on this subject from the point of view of a dermatologist in a paper which I read in St. Louis some time ago. I am satisfied that many things which are not clearly understood in the statistics of nervous diseases may be better understood if we consider the parallel statistics of the Wassermann reaction in cases of syphilis.

The first reports on the Wassermann reaction brought very interesting divergencies in the findings. While Neisser found the reaction positive in 70 per cent. of recent, clinically well-established cases of syphilis, Wassermann found it positive in 90 per cent. If two founders of a method, working on the same principle, come to such enormous difference—I do not mention the varying statistics of other and later investigators—while using entirely fresh syphilitic material, is it any wonder that one finds such divergence in the results of the sero reaction in cases of nervous diseases, where a supposedly acquired luetic infection occurred years and years ago, if at all, and the ways and means of establishing an eventual syphilitic origin of the disease, either clinically or by any other method, is very difficult?

In Professor Reilly's recent publication from the Leipsic clinic for internal diseases, it is stated that in the course of investigations in connection with syphilis, the seroreaction, eight cases of tuberculosis were examined as to the complement *binding of their serum, which is the principle of Wassermann* reaction. The results even in these few cases were striking: 3 gave a strong positive Wassermann, *i. e.*, hemolysis did not take place at all; 3 others gave a reaction of medium degree and the remaining 2 a weak reaction. In other words, over 35 per cent. of cases yielded a strong positive reaction. Salomon, chief of von Noorden's clinic for internal diseases in Vienna, reported at the Congress for Internal Medicine, held in Vienna in May, 1908, that he found a positive Wassermann reaction in 5 out of 23 cases of tuberculosis, which is a considerable percentage. If you consider for a moment the prevalence of consumption in the large cities in this country, as well as in Europe, especially in those strata of population which provide the clinics for venereal diseases with their material for investigation, you can imagine how the statistics of positive Wassermann reaction might be influenced, if in every case of syphilis it would be stated whether tuberculosis were present or absent. Therefore, so long as the statistics of the Wassermann reaction lack one important feature, viz., the statements regarding the general condition of the patients as to exclusion of any other disease which has already been found or may be found in the future as giving the reaction in a rather large number of cases, they must be considered with less enthusiasm than the ardent followers of Wassermann would like to see. The seroreaction has already lost the scientific foundation which Wassermann originally claimed for it and is an empirical method that promises to become a valuable aid to clinical diagnosis. But its specificity for syphilis is more than doubtful. A voice of warning must therefore be sounded, because boundless enthusiasm is apt to discredit a method which at present is only in its inception and which through a judicious criticism will gain more than through a criticless admiration.

Dr. Maximilian Herzog, Chicago: I have had some experience with the Wassermann test, having tried it in about 100 cases of which I have more or less complete clinical histories. I want to go on record with the statement that Noguchi's modification, commendable as it is from a purely scientific standpoint, is a very dangerous thing because it tends to place in the hands of the general practitioner a test which is exceedingly difficult, a test which involves some very delicate principles and which can never be made a simple test, as has been pointed out. I have had some experience with one modification, that of Bauer, and while I can not go into the details here of the defects I found in that modification in comparison with the original Wassermann test, I can state that from what I have seen, none of those modifications ought to be used, and we ought to stick to the original Wassermann test, which has already been tried in many thousands of cases. We have from four European clinics alone the reports of 10,000 cases.

Now, so far as my material is concerned, from the standpoint which interests you, it has been rather scanty. Most of my cases were of the ordinary cutaneous type and they came from the hands of the dermatologist; but I have examined 8 cases of tabes of which 6 were positive and 2 negative; the 2 cases which were negative were patients who had been treated with mercury and the iodids. I had 3 cases of early paresis. All of those reactions were positive. The other cases examined were of doubtful types and they were all negative, but all of those were proved finally not to be cases of syphilis. So, on the whole, I can confirm on a very small number of cases of tabes and paresis those larger statistics on these parasyphilitic affections given here to-day.

In conclusion I want to urge you to stick for a while at least to the original Wassermann test. Let it be made by men competent to make it and let us not take any statistics from men who say that they find that 25 per cent. of their cases of tuberculosis give a positive reaction. A positive reaction by the Wassermann test means syphilis and nothing else, except, of course, an occasional case of scarlatina, leprosy, etc. A man who gets 25 per cent. positive reactions in tuberculosis doesn't know how to make the test.

DR. B. SACHS, New York: I have very little to add except that the remark which the last speaker made, I think, has a great deal of truth in it; that if any one were to claim that he had found 25 per cent. of tuberculosis cases giving a positive reaction under the Wassermann test, personally I should be very much inclined to doubt the accuracy of his test. The only safe position for all of us to assume is that this entire question is in its earliest stage; and the one reason why I was very glad to help bring this subject before the meeting to-day was to encourage as many men as possible to take up the line of investigation; and I think we shall only arrive at the truth of the matter after we shall have had statistics upon thousands and thousands of cases. It will be much the same, I think, as it was at the time of the agitation in favor of the adoption of the Widal method in the diagnosis of typhoid. Everyone now knows about how much importance to attach to a positive or negative reaction in typhoid.

In order that my own view may not be misunderstood, I would like to say that I agree with those who favor retaining the Wassermann method, and I hope that everyone who works in this field will take the trouble to acquire the original method. But I also want to say, as one who has personally worked in this field and who has tried to do conscientious work in it, that I hail with delight Dr. Noguchi's attempt at a modification of the method, and chiefly for the reason that everyone who works with the Wassermann method knows how difficult it is at various times to obtain satisfactory material for reagents. I think the suggestion made is perfectly correct. The method should be designated as the Wassermann test in deference to Wassermann, who did the great original work in this field, while the method described by Dr. Noguchi should be called the "Noguchi Modification of the Wassermann test." Dr. Noguchi's idea of trying to dry these various reagents, preserve and have them handy for use at all times is one that I can only admire. I would suggest that everyone who works with the Noguchi modification should for the next year or two use it and control it by a parallel series of tests according to the original Wassermann reaction. In that way, and by making comparison between the two methods, we will in time learn whether the Noguchi method can be accepted as a full substitute for the Wassermann reaction. In a parallel series of my own of a large number of cases, the agreement between Noguchi's modification and the original Wassermann test was very remarkable indeed. The differences were confined to three or four instances and such differences can readily be explained. They were so slight that I want to go on record as much impressed by Noguchi's modifications. But I plead in favor of running the two tests side by side for a considerable period.

DR. H. NOGUCHI: I regret very much that Dr. Castelli appears so far to misunderstand my attitude toward the original Wasserman method as to speak of me as a bitter critic. My attitude is simply this: I recognized certain defects inherent in the Wassermann method, and what I have done is to improve that method by eliminating these defects. My criticism is a criticism of the principles involved in the technic and not of the persons employing it; and hence there is no bitterness in my criticism. Dr. Castelli has also referred to the work of those whom he refers to as my pupils. In the usual sense of the word, I can not be said to have had pupils. Dr. Castelli himself, however, did some tests in my laboratory before I completed my new method. The Wassermann reactions reported by him have been done, I believe, largely with the titrated amboceptor and antigen which I furnished. A number of other physicians, who have worked with me over a period of several months, have learned not merely the procedure employed in doing the Wassermann and my own method of the fixation test, but also the principles of hemolysis, and the method of preparing the antigen, amboceptor, and complement, but are, I feel justified in considering, capable of carrying out the serodiagnosis of syphilis in a reliable manner.

In my opinion forty cases are hardly enough to base any final conclusion on. Besides, the slight discrepancy between the results obtained by Dr. Castelli and those by me may also be ascribed to the individual differences. I doubt whether Dr. Sachs would have obtained a better agreement of the results if he had sent these specimens to two different persons employing the same method. That my system is more sensitive than the Wassermann is, however, clear from my own comparative study on 244 cases, but there is no undue sensitiveness in the system.

I had perfected my system before Tschernogubow's article appeared, and I may point out that Tschernogubow's method is fundamentally incorrect in its principles. Not one case has been reported by him and he has now another method in which he proposes to use guinea-pigs' washed corpuscles.

Concerning Dr. Herzog's warning of the danger of abuse of the reaction on account of simplification, there can be no more danger in this than in the difficult Wassermann test, so long as both are to be carried out by trained workers only. The simplification removes the difficulties for these qualified workers, and offers a better opportunity to untrained men to become qualified within a shorter period. There is no guarantee that the difficulties in the Wassermann method will necessarily bar unqualified workers.

Clinical Notes

TWO CASES OF TUBERCULOUS INFECTION OF THE PERITONEUM

W. H. ALLPORT, M.D.
CHICAGO

These cases illustrate unusual phases of intraperitoneal tuberculosis, and serve also to draw attention to certain points in the natural history of this disease which do not appear to have received sufficient notice at the hands of systematic writers.

HYPERTROPHIC APPENDICITIS OF TUBERCULOUS ORIGIN

CASE 1.—*History.*—S. R., boy aged 10, had had numerous previous attacks of appendicular colic, and a history of "not feeling well" for one month, with the present acute attack of three days' duration.

Examination.—Patient was rather pale and emaciated; pain, vomiting, constipation, tense rectus, indistinct tumor at McBurney's point. Afternoon temperature, 102 F.; leucocytosis, 20,000.

raw rectal wall was at once carefully examined, but no bowel opening could be detected, and after closing the opening in the cyst with forceps, the enucleation was completed. There was no hemorrhage from any single large vessel, although the oozing from torn surfaces was profuse. The tumor had been contained in a sort of globular cavity made up of pelvic wall, sigmoid and rectum, bladder and uterus, and there was not the least suggestion of pedicle. The adjacent bowels were then cleaned and examined for perforations, but, although the surfaces were unhealthy and denuded, they presented no macroscopic tubercular nodules and no perforation could be discovered. Three cigarette drains were introduced, two to the depths of the cavity and one to the most suspicious bowel surface, and the abdomen was closed after excising the hernial sac and renewing the normal relations of all the parietal structures to the median line. The operation was followed by great vascular shock and considerable vomiting and distention, but in five days improvement was coincident with the appearance of a fecal fistula, through which escaped, at first, all of the evacuations and large quantities of flatus. Presently, however, the rectum resumed its function, the temperature became continuously normal, the appetite and strength improved, the fecal discharge ceased, and at the present writing conditions point toward a speedy permanent wound healing under occasional treatment of the fistulous tract with Beck's paste. Weight, 124, and increasing.

Examination of Specimen.—Smaller cysts (2 or 3) not preserved, but filled with clear contents; walls unthickened. Contents of large cyst not preserved, but of fecal odor, gray-brown color, not bloody, and about the consistency of buttermilk. Size, prior to rupture, that of an ordinary cocoanut; after removal, that of a baseball. Outline, irregularly globular; no pedicle; surface rough and fibrous, with no peritoneal surface in evidence. Thickened areas in the wall were later recognized microscopically as tube and ovary. Sac wall, irregularly thickened, fibrous and varying from .5 to 5 cms. (1/5 to 2 in.) in thickness; some soft spots containing blood and pus; a fistulous tract 4 cm. (1½ in.) long, lined with grayish-green membrane and terminating abruptly on inner and outer faces of sac. The interior of the cyst is rough, irregular and gangrenous, and the wall in places peels rather readily into layers.

COMMENT

The original pathologic diagnosis made by the laboratory in this case was pyosalpinx and pelvic abscess. Later Dr. E. R. LeCount, without knowledge of the clinical history, became suspicious of the specimen and took up the microscopic examination himself. After repeated section cutting, he was able to demonstrate:

(a) Many microscopically typical foci of tuberculosis were present with no gross tuberculous degeneration.

(b) The cyst was neither covered nor lined with epithelium or endothelium, and that its wall was made up of layers of organized fibrin and inflammatory cells.

(c) The tube and ovary were incidentally included in the cyst wall, but that they did not form any integral part of the cyst.

(d) The tube and ovary were not themselves tuberculous.

The findings at the first operation were those of the ordinary form of tuberculous peritonitis, probably secondary to intestinal tuberculosis. At the second operation the gross tuberculosis had disappeared, leaving the usual scar-tissue adhesions. At the third operation the pathologic finding was an extremely rare one: a pseudocyst composed of tuberculous inflammatory tissue, probably originating from an encapsulated perforating ulcer of the sigmoid, and fed from time to time with septic material from the bowel.

Such pseudocysts are mere sacculated receptacles for morbid products, and are to be differentiated from true cysts of the genital tract by their lack of true lining and covering membranes, by the thickness and inelasticity of their walls, and by the wall itself being composed entirely of inflammatory material. Their origin is usually tuberculous. Clinically, these deposits are commonly taken for ordinary pelvic cysts, or for tubo-ovarian abscesses, and there is no possible way to identify them prior to operation, except through inferences drawn from the history.[2]

CRURAL AND AXILLARY RINGWORM IN THE CANAL ZONE

ALFRED G. FARMER, M.D.
Physician, Gatun Dispensary, Isthmian Canal Commission
GATUN, CANAL ZONE

Mention in The Journal of June 26, 1909, of the prevalence of tinea cruris in the temperate zone would seem to make some description of this annoying disease, as seen so commonly in the tropics, of interest. Tinea cruris et axillaris is seen with great frequency among the laborers and lower class of natives in the Canal Zone, and it is by no means uncommon among the natives of the North resident here. The disease flourishes best among those of uncleanly habits and improper and careless personal hygiene. The practice of this class of persons of washing their clothing in streams and pools and of spreading it on the usually moist ground and grass to dry seems to provide a ready means of infection. The infrequency of change of clothing and of bathing may also be mentioned as predisposing factors.

The disease usually appears first, as the name implies, on the inner side of the groin next the body and in the armpits, rapidly spreading, if neglected, over the scrotum, thighs and trunks. Patients frequently present themselves for treatment who have two-thirds of the body surface affected. There first appears a small reddish area of inflammation with slightly raised edges, these spots gradually spread peripherally till they reach the size of a silver dollar or of the palm of the hand. The inflammation in the center of the "circle" recedes as the periphery enlarges. In neglected cases new areas of infection soon appear in the near vicinity and as they enlarge the rings coalesce, forming one large infected area of joining rings. The intense itching, especially at night, makes this disease most annoying and often causes badly infected sores and ulcers as a result of lacerations by the finger nails in an effort to find relief. The tinea cruris et axillaris as seen here does not usually destroy the hair follicles.

The treatment is prophylactic and active. Bathing and changing the underclothing should be practiced at frequent intervals, and all clothing should be thoroughly boiled in the laundry and hung on lines to dry. Effective active treatment will be obtained by cleaning the parts thoroughly with the tincture of green soap and water and applying with some friction the ointments of sulphur or salicylic acid or iodin, this procedure to be repeated once or twice daily for several days, or when comparatively small areas are involved and the individual is of sufficient hardihood to stand the few moments of severe burning, a thorough painting with the tincture of iodin or a solution of salicylic acid in alcohol and ether will very promptly eradicate the fungus. The latter measures sometimes give rise to a troublesome irritative inflammation that will require for a few days the application of one of the mild ointments, as boric acid or 1 per cent. carbolic acid in petrolatum.

---

[2] Koenig: Spec. Chir., II, 155, 1889.

Operation.—Incision over tumor revealed an old chronic appendix of such enormous thickness that it was taken at first for a loop of small intestine. The abdomen contained some clear fluid. The appendix was surrounded by dense adhesions protecting several perforations, and on removal measured irregularly 3.5 cm. (1½ in.) in diameter by 12 cm. (5 in.) in length. At its point of origin from the bowel it was of normal caliber. Section showed it to be composed of dense fibrous tissue, surrounding numerous cheesy foci and tubercular granulations. The perforations were apparently not due to pressure necrosis, but to a slow extension of the tuberculous process entirely through the wall of the tube. The raw surfaces left after removing the appendix oozed so freely that gauze drainage was introduced.

Subsequent History.—This represents a slow, but complete and natural recovery from a tuberculous infection, after surgical removal of the major focus. The patient remained under daily observation for twelve weeks; during this time there was a temperature range from 98 F. in the morning to 102 F. in the afternoon, with night sweats. The urine showed constantly a large amount of indican, but no sugar or albumin. The leucocyte count varied for many weeks from 27,000 to 48,000, but the percentage of polymorphonuclear leucocytes was never far from normal. After eight weeks the wound closed, but the temperature and blood count remained so high and the obstructive symptoms were so suggestive that in the tenth week the incision was reopened in the expectation of finding a subphrenic or mesenteric abscess. Nothing was found beyond numerous adhesions and ropes of knotted omentum, which were partially resected and broken up; otherwise, the intraabdominal conditions were very satisfactory, and the wound was closed after freshening all muscular edges to insure protection against subsequent incisional hernia. The second operation had little effect on the progress of the case, except to relieve the partial obstruction; the temperature slowly subsided; the appetite, strength and flesh returned; and for over four years the patient has been to all appearances in the best of health.

COMMENT

This very unusual appendix was the product of an effort to accomplish the inclusion of certain tuberculous foci within a zone of resistance and protection. Undoubtedly the process was over-developed, and resulted in a general fibrous hypertrophy of the entire organ.[1] Hypertrophic appendicitis is of two varieties: (1) a form based on obstruction, in which the muscle fiber is increased through the stimulus of resistance to peristaltic action at the point of obstruction; and (2) a form in which diseased foci are surrounded by protective zones —more or less coalescent—of granulation and fibrous tissue. More commonly the diseased focus originates in a foreign body, but in rare instances, like the present, the irritating material from which exclusion is sought is represented by colonies of the *Bacillus tuberculosis.*

The important clinical points to be noted are: (a) That in spite of the chronic process the onset was apparently sudden, so far as the call for medical aid was concerned; (b) that the case prior to operation gave little hint of the tuberculous source of the trouble; (c) the long-continued postoperative temperature and phenomenally high leucocytosis were incorrectly inferred to represent further mixed infection with abscess formation. In reality they represented a virile and eventually successful resistance to such of the tuberculous material as remained active within the peritoneum after the removal of the principal deposit.

Safe general rules to deduce from this case are: (1) A sharp rise in temperature and leucocyte count, after operations for tuberculous conditions, indicates vigorous resistance, and, other things being equal, should influence a favorable prognosis. (2) Secondary operations, in tubercular cases, unless for well-defined obstruction, are not indicated on the sole basis of fever or high leucocytosis.

TUBERCULOUS PERITONITIS WITH LARGE PSEUDOCYST, AND CHRONIC OBSTRUCTION

Case 2.—Illustrating, (a) ascitic form of tuberculous peritonitis with adhesions; recovery after exploratory incisions, followed by (b) encysted deposit communicating with bowel, "tubercular pseudo-cyst."

History.—In 1906, Dr. W. H. Sands of Fairmount, W. Va., made a laparotomy on R. J., an otherwise apparently healthy young woman, aged 22, unmarried and undoubtedly a virgin. He found a miliary tuberculous peritonitis, extensive in character, moderate ascites, and dense fibrous adhesions between intestines and all the pelvic organs. He removed nothing, dusted well with iodoform and closed without drainage. She left the hospital in three weeks. A mucopurulent discharge from the bowel developed and in eight months she was again operated on, this time for obstruction. Prior to Dr. Sands' second operation she was seen by the writer, who can vouch for her apparently desperate condition. She was of a waxy pallor; the bowels were distended and the abdomen very tender; the evening temperature was high; the bowel movements were scanty or mucopurulent, and the patient was allowed to go to her home on the theory that she was fatally ill with peritoneal and intestinal tuberculosis. On reaching home Dr. Sands broke up many of the adhesions, found no evidence of the former miliary tuberculosis, dusted with iodoform and closed. Recovery again was uneventful. In six months Dr. Sands again saw her with several large joints involved in an apparently tuberculous arthritis. At this time there appeared to be some involvement of the lung. No operation. Weight, 105 pounds. On the subsidence of the arthritis she was sent to the mountains where she remained one year. She then returned to Chicago and came to my office to get work as a nurse. She was a picture of exuberant health—plump, ruddy and vigorous. Weight, 130. Within a month she was again taken with symptoms of acute obstruction and her subsequent history is as follows: Temperature, from 100 to 103 F.; tongue clear; nausea and vomiting frequent; constipation obstinate, but not unyielding; abdomen distended, but rigid and tender only below the line of navel; urine dark brown with strong reaction for indican, no albumin; movements contained some mucopus. In lower left quadrant in the region of the sigmoid there was a swelling, round and tender, about the size of an infant's head at term. Blood count: 18,000.

Diagnosis.—Infected cyst; obstruction from combined effect of chronic adhesions and enlarging cyst.

Treatment.—Under hot applications and a starvation diet the symptoms improved for a few days, and there was some reduction in the size of the tumor, coincident with free evacuations from the bowel, containing pus. But presently the temperature again mounted and the patient was taken to the hospital for operation. A median incision through the old scar —which was hernial—opened a smooth non-tuberculous peritoneal sac, containing a little clear fluid, and traversed by numerous bands and layers of old adhesions, obliterating effectually all organs and landmarks. During the subsequent manipulations neither uterus nor ovaries were recognized as such. The excised mass seemed to be an ordinary infected cyst of the right ovary or broad ligament, which had developed in the usual manner but had assumed rather peculiar relations toward the sigmoid colon in consequence of previous tuberculous infection. The tumor was completely wrapped in the sigmoid flexure; the omentum was not encountered during the operation. With great difficulty a line of cleavage was secured along the anterior aspect of the tumor, and the growth was literally dug out of the pelvis. Several small thin-walled cysts, containing clear fluid and lying apparently close against the uterus were also enucleated; these had no connection with the larger tumor except by contiguity. While separating the tumor from the upper part of the rectum, the adhesions were so close that the cyst wall gave way, allowing a quantity of brownish fluid of fecal odor to escape. The raw rectal wall was at once carefully examined, but no bowel opening could be detected, and after closing the opening in the cyst with forceps, the enucleation was completed. There was no hemorrhage from any single large vessel, although the oozing from torn surfaces was profuse. The tumor had been contained in a sort of globular cavity made up of pelvic wall, sigmoid and rectum, bladder and uterus, and there was not the least suggestion of pedicle. The adjacent bowels were then cleaned and examined for perforations, but, although the surfaces were unhealthy and denuded, they presented no macroscopic tubercular nodules and no perforation could be discovered. Three cigarette drains were introduced, two to the depths of the cavity and one to the most suspicious bowel surface, and the abdomen was closed after excising the hernial sac and renewing the normal relations of all the parietal structures to the median line. The operation was followed by great vascular shock and considerable vomiting and distention, but in five days improvement was coincident with the appearance of a fecal fistula, through which escaped, at first, all of the evacuations and large quantities of flatus. Presently, however, the rectum resumed its function, the temperature became continuously normal, the appetite and strength improved, the fecal discharge ceased, and at the present writing conditions point toward a speedy permanent wound healing under occasional treatment of the fistulous tract with Beck's paste. Weight, 124, and increasing.

---

[1] A similar case is reported by Murphy in the Am. Jour. Obstet., 1904, xlix.

Examination of Specimen.—Smaller cysts (2 or 3) not preserved, but filled with clear contents; walls unthickened. Contents of large cyst not preserved, but of fecal odor, gray-brown color, not bloody, and about the consistency of buttermilk. Size, prior to rupture, that of an ordinary cocoanut; after removal, that of a baseball. Outline, irregularly globular; no pedicle; surface rough and fibrous, with no peritoneal surface in evidence. Thickened areas in the wall were later recognized microscopically as tube and ovary. Sac wall, irregularly thickened, fibrous and varying from .5 to 5 cms. (1/5 to 2 in.) in thickness; some soft spots containing blood and pus; a fistulous tract 4 cm. (1½ in.) long, lined with grayish-green membrane and terminating abruptly on inner and outer faces of sac. The interior of the cyst is rough, irregular and gangrenous, and the wall in places peels rather readily into layers.

COMMENT

The original pathologic diagnosis made by the laboratory in this case was pyosalpinx and pelvic abscess. Later Dr. E. R. LeCount, without knowledge of the clinical history, became suspicious of the specimen and took up the microscopic examination himself. After repeated section cutting, he was able to demonstrate:

(a) Many microscopically typical foci of tuberculosis were present with no gross tuberculous degeneration.

(b) The cyst was neither covered nor lined with epithelium or endothelium, and that its wall was made up of layers of organized fibrin and inflammatory cells.

(c) The tube and ovary were incidentally included in the cyst wall, but that they did not form any integral part of the cyst.

(d) The tube and ovary were not themselves tuberculous.

The findings at the first operation were those of the ordinary form of tuberculous peritonitis, probably secondary to intestinal tuberculosis. At the second operation the gross tuberculosis had disappeared, leaving the usual scar-tissue adhesions. At the third operation the pathologic finding was an extremely rare one: a pseudocyst composed of tuberculous inflammatory tissue, probably originating from an encapsulated perforating ulcer of the sigmoid, and fed from time to time with septic material from the bowel.

Such pseudocysts are mere sacculated receptacles for morbid products, and are to be differentiated from true cysts of the genital tract by their lack of true lining and covering membranes, by the thickness and inelasticity of their walls, and by the wall itself being composed entirely of inflammatory material. Their origin is usually tuberculous. Clinically, these deposits are commonly taken for ordinary pelvic cysts, or for tubo-ovarian abscesses, and there is no possible way to identify them prior to operation, except through inferences drawn from the history.[2]

CASE OF LYMPHATIC LEUKEMIA

H. H. HAZEN, M.D.
WASHINGTON, D. C.

On account of the marked blood picture the following case of lymphatic leukemia seems worth reporting:

Patient.—M. D., aged 60, Irish, a watchman. The family and past history are both unimportant. The patient denied any venereal disease and had never used alcohol. He had always been a strong, healthy, hard-working man.

Present Illness.—During the summer of 1903 he noticed enlarged glands in the neck, axillæ and groins, together with slight weakness. He had been unsuccessfully treated by several physicians. He first came under observation Oct. 28, 1904, complaining of general weakness, epistaxis and enlarged glands. He was put on potassium iodid, and in two weeks the glands had become smaller and softer; they soon regained their usual large size, however. The probable diagnosis of leukemia was made and the patient was put on Fowler's solution, which did not help him.

Examination.—Late in November I saw the patient. He was a well-nourished man, with skin a trifle bronzed, lips and mucous membrane extremely pale. Lungs and heart were normal; abdomen was distended with fluid; the liver was not palpable, but the spleen extended a full hand's breadth below the costal margin. In the anterior triangles of the neck there were enlarged glands, some being as much as 6 cm. long. They were discrete and very hard; the axillary and inguinal glands were also markedly enlarged. From neither the history nor examination was there any evidence of involvement of the mediastinal glands. The legs were slightly edematous; the urine was absolutely normal. One month later a blood examination was made, with the following results: Hemoglobin, 20 per cent.; red cells, 960,000; white cells, 250,000. A smear showed the red cells to be normal in appearance; no nucleated reds and no megaloblasts were seen. The predominating white blood cells were small mononuclear non-granular cells, typical lymphocytes. Only two polymorphonuclears were seen. There were no eosinophiles, no mast-cells, no large mononuclears, and no myelocytes.

Course of Disease.—While I did not see the patient again, I am informed by his physician that he grew steadily weaker, that he had severe attacks of epistaxis and that his liver became enlarged. Death took place on Feb. 12, 1905. No autopsy was permitted.

1204 Eighteenth Street.

TUBERCULOSIS EXHIBIT AND CABINET

FRANK B. WYNN, M.D.
INDIANAPOLIS

This descriptive article is published as a means of answering numerous inquiries concerning the tuberculosis exhibit shown at the recent American Medical Association session in the name of the Indianapolis Medical Society. As will be seen from the picture, the exhibit is housed in a handsome and substantial cabinet, consisting of an upper show case in which are placed models of pavilions, shacks, tents and devices used in the treatment of tuberculosis. Appended to each of the models are brief data as to materials and cost of construction. At one end of the cabinet is a flashlight transparency, which announces that with the lapse of every three seconds another victim has been claimed by tuberculosis.

The lower half of the case consists of two drawers, 10 by 14 by 22 inches in size, opening on opposite sides of the case. This enables several persons to be examining the contents of the drawers at the same time. In these drawers are anchored (similar to any index file) a hundred or more heavy cards on which are photographs, cartoons and diagrams with appropriate descriptions, statistical data, mottoes, sanitary dicta, etc., relating to the whole problem of tuberculosis.

Signs in the glass case call attention to the drawers below where the observer is invited to learn the story of the great white plague. A smaller cabinet embodying the same principles can be manufactured for at least half the price of the larger one.

Marvelous strides have been made in preventive medicine during the past two decades through the usual health board [illegible]. circulars, popular lectures and tl [illegible] these means are being supplemented by exhibits relating to public health problems—notably tuberculosis. While they represent the most efficient means thus far employed to enlighten the public on sanitary questions, they are open to the serious objection of cumbersomeness and expense in maintenance. They are presented for a few days in the community and perhaps never again. Such spasmodic efforts can not bear the good fruit that would arise from means which could keep the question constantly before the people.

DISADVANTAGES OF PAST METHODS

As a concrete example take the exhibit of the New York Charities Organization. It is the most complete and comprehensive that has been devised in this country. Installed for a few days now in one part and now in another part of New York City, it has been of incalculable value in teaching, especially the lower classes, the story of tuberculosis in all its aspects. But however excellent, a fair criticism of the practicability of this exhibit (and similar ones) may be made on the following grounds:

1. Its primary cost, which must have been from $1,200 to $1,500.
2. The cost of housing—a large room being necessary.
3. Expense of moving, installing and proper supervision. (The cost of its presentation at the Atlantic City meeting of the American Medical Association was over a hundred dollars.)
4. The short period of time during which it is maintained in any given place.

ADVANTAGES OF THIS EXHIBIT

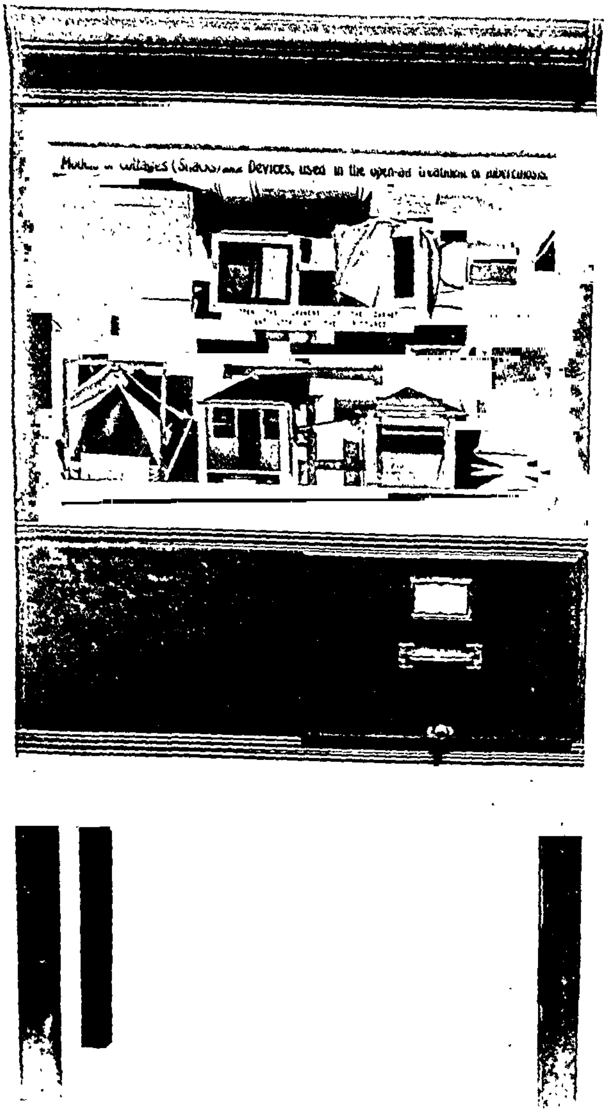
To overcome such objections as the foregoing the Scientific Exhibit Committee of the American Medical Association has for the past two years been endeavoring to interest sanitarians in developing a compact but comprehensive tuberculosis exhibit. Five were offered at the last meeting, each having distinct points of merit. The one herein described does not fulfill all requirements, but I believe has much to commend it. The advantages may be summarized as follows:

1. Compactness, neatness and stability: The cabinet takes up but little room and can stand with safety in any public building where crowds congregate.
2. Completeness: Although compact, it can be made to contain as much as the large exhibits—all that is necessary for the instruction of the public.
3. It requires no supervision, but tells its own story graphically.
4. Cost: If manufactured in large numbers, they could be sold at a figure sufficiently low to enable health boards to place them in railway stations, court-houses, public libraries and like places.
5. The continuity of effort would bring home to the people the lessons of the tuberculosis problem every day of the year.
6. The same cabinet might be used as occasion required for instruction on other sanitary matters.

PROBLEM OF PRODUCTION

To the many inquiries which have been made as to the cost of these cabinets and where they may be obtained, no satisfactory answer can be made. Two large concerns have made overtures looking to their manufacture. In order to secure the widest possible educational effect, it is desirable that the exhibits be sold almost at cost to insure their general use. Is it practicable to attain this end? Why should not the Board of Trustees of the Association, the Scientific Exhibit Committee or other regularly constituted representative undertake the supervision of this undertaking? Let them ascertain through experts the lowest figure at which these cabinets, equipped, can be made. Then secure an agreement from some reputable firm to market them at this price.

The Association's endorsement would insure large sale. Let the manufacturer pay the Association a royalty to cover the expense of proper supervision of the data that go into the cabinets. These would need to be varied to suit localities and states. Such supervision would insure the introduction of such matter only as would be prudent and sane; sufficiently instructive to the lay mind on tuberculosis and other sanitary questions, but so tempered as not to excite ridicule or unnecessarily alarm the people on such matters. It would offer the Association an opportunity to render most effective cooperative aid to health authorities and, therefore, would prove of great service in the march of preventive medicine—a field in which the Association, as an organization, has as yet done but little.



Models of Cottages (Shacks) and Devices, used in the open-air treatment of tuberculosis.

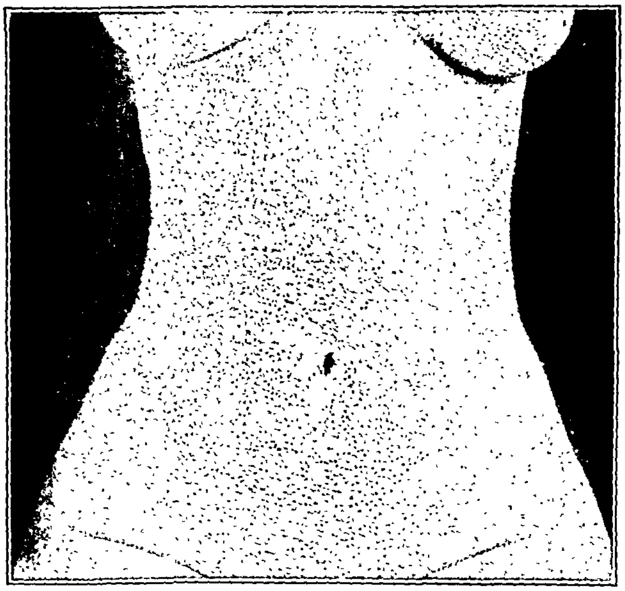
A CASE OF SYPHILIS RESEMBLING PITYRIASIS RUBRA PILARIS

HOWARD FOX, M.D.
NEW YORK CITY

The following case of miliary papular syphilis is of interest on account of its very close resemblance to the papular stage of pityriasis rubra pilaris. When seen in August, 1908, at the Vanderbilt Clinic, the patient, a widow of 30, presented a general eruption of the face, trunk and extremities. This consisted, for the most part, of small, conical, pin-head papules, capped with horny scales. There was no tendency for the lesions to become confluent and there were no signs of itching. On the face there were erythematous and scaly lesions that might have occurred with either of the diseases in question. There was no history of any genital sore, no glandular enlargement and no lesions of the mouth. The palms were thickened and scaly, but did not present the appearance characteristic of the early palmar syphilide. While the eruption simulated a pityriasis rubra pilaris very closely, it was noticed that there was a slight tendency of the papules to follicular grouping so characteristic of miliary papular syphilide. Further, the appearance of the backs of the phalanges generally noted in pityriasis rubra pilaris was absent.



A case of miliary papular syphilis in which the eruption simulated pityriasis rubra pilaris.

When the case was first seen I had not begun to work with the Wassermann test, and a clinical diagnosis alone was possible. To show the great difficulty in diagnosis it may be said that a distinguished dermatologist of the city pronounced the case to be unquestionably one of pityriasis rubra pilaris. The patient was kept under observation for two weeks, at the end of which time the lesions began to show a tendency to become papulosquamous, and she was then put on antisyphilitic treatment; within a month the greater part of the eruption had disappeared. The patient then became somewhat irregular in attendance at the clinic,

and a few weeks later developed a rather severe iritis. For the privilege of reporting this case I am indebted to Dr. George T. Jackson.

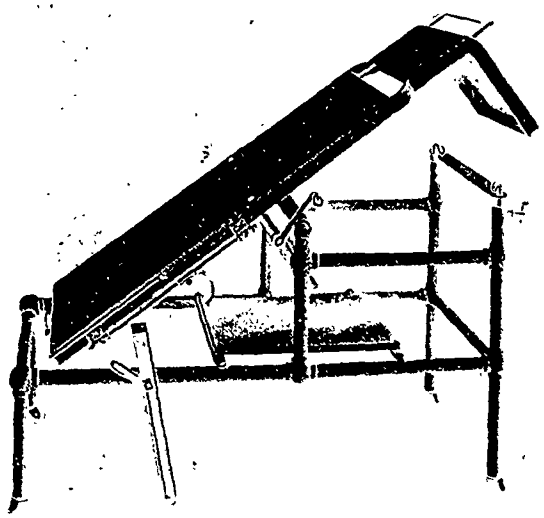
AN OPERATING-TABLE

D. TOD GILLIAM, M.D.
COLUMBUS, O.

The special features of this table are:

1. An extension rod which slides in and out at the foot of the table.
2. The leg-holders, which fit into the posts and which can be set at any height by means of a set-screw.
3. A revolving instrument tray which is attached to the leg-holder can be raised or lowered at will.
4. The body-lift, plain, or provided with movable side brackets to fix the kidney during operation and to keep the patient from rolling.
5. The shoulder-supports, small, neat and movable. They are hinged at the sides of the table and can be adjusted immediately for use or turned under the table out of the way.
6. A support for rectal treatment or for maintaining the knee-chest posture. This is effected by a strap extending from one leg-holder to the other at a proper height; the patient kneels on the shelf covered by a blanket, his body thrown forward over the strap.



An improved operating-table.

7. The shield between the anesthetist and operator, which fits snugly around the end of the table when not in use, and which can be raised to the vertical or any desired angle and fixed by a set-screw when needed.

The extension rod at the end of the table has many uses:

1. In vaginal or rectal operation a towel thrown over it protects the sutures from contact with the drop.
2. Drawn out a little further it makes a foot-rest for the patient in examination or treatment.
3. It holds a douche-pan in vaginal or rectal operations.
4. Pulled out so as to allow the legs to be lowered through it and strapped to the drop, the same douche-pan, placed between the end of the extension rod and the patient's knees, acts as a receptacle for soiled sponges in abdominal operations.
5. By placing the shelf from under the table on it and adjusting the extension rod to the length of the patient, a full-length table is obtained exactly fitted to his stature.

Every attachment is an integral part of the table and always at hand, there being no pieces to lay aside and gather up when needed. Also there are no hinged leaves or other unstable parts to the table.

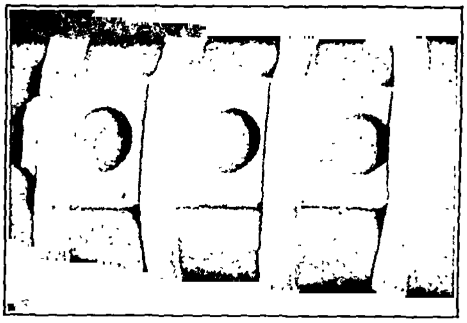
50 North Fourth Street.

A PROTECTOR FOR USE IN THE CUTANEOUS TEST FOR TUBERCULOSIS

R. L. SUTTON, M.D.
KANSAS CITY, MO.

In applying the cutaneous test for tuberculosis, the scarified surfaces, unless covered, are subjected to irritation and possible infection from without.

Protection usually is secured by the use of a soft, smooth dressing, as a linen or silk handkerchief, applied as a bandage directly over the wound. While this method serves very well in many instances, it is open to some objections. The cloth comes closely in contact with the excoriated surfaces and is liable to irritate, causing misleading inflammation; the dressing is difficult to keep in place, especially on the forearm (the part commonly selected); and the progress of the reaction can not be observed without removing the bandage.



Protector for use in the cutaneous tuberculosis test.

I have found an oblong felt protector, like the one shown in the accompanying illustration, of considerable value. It is made on the same principle as the widely used vaccination pads, and the openings are covered with thin, transparent celluloid. The dressing is firmly held by four short, transverse strips of adhesive plaster.

SEVENTH ANNUAL SUMMARY OF FOURTH OF JULY INJURIES

For the seventh consecutive year we are presenting statistics of injuries received during the celebration of the Fourth of July, with particular reference to tetanus resulting from these injuries. Considerable effort has been made to secure reliable data, and all serious cases have been carefully investigated, so that, so far as the figures go, dependence may be placed on them. We have received thousands of letters from physicians in all parts of the country, reporting cases which otherwise could not have been included in the statistics. There are doubtless thousands of other cases not reported, although chiefly minor injuries. Our thanks are due for the many careful reports which have made these statistics more complete and the figures more reliable. The data are presented in the same manner as heretofore, in order that comparison may be made.

MORE CASES OF TETANUS

There were 150 tetanus cases this year, almost double the record of last year, when 76 cases were reported. This is the largest number since 1903, when there were 415 cases. It is significant to note that the number of blank cartridge wounds correspondingly increased from 816 last year to 1,095 this year, and that the states having the largest numbers of blank cartridge injuries have

also the largest numbers of tetanus cases (Table 5). It is interesting also to state that from blank cartridge wounds there was a higher percentage of deaths (10.2) than from gunshot wounds (6.1 per cent.).

The most common cause of the wound is the blank cartridge, and the usual site is the hand. The duration given is the number of days between the injury and death or recovery. Following the injury it required from 5 to 15 days before the symptoms of tetanus appeared, the average of all fatal cases being about 7 days. The longer
